ORIGINAL ARTICLES.

THE PRODUCTION OF BRONCHIAL BREATHING IN CONSOLIDATION AND OTHER CONDITIONS OF THE LUNGS.[1]

BY CHARLES CARY, M.D.,
OF BUFFALO, N. Y.

THE title of this paper is perhaps subject to misconception. It includes the discussion of the physical principles involved in the production of tubular breathing, and suggests that these same principles induce the broncho-vesicular and cavernous breathing, which differ from the first only in degree. There has been some little controversy upon this subject, limited, however, largely to those authors that have practical minds and a fancy for acoustics. Most of our modern text-books contain descriptions of the sound, and account for its production by quoting one of the few authorities that have written on the subject. The explanation offered by Laennec, and still held by some, was that the sound was produced by the vesicular murmur being cut off and the tubular or bronchial sound alone being audible. In the fourth edition of his work he expresses himself as follows: "The sound observed in the larynx, trachea, and larger bronchial trunks is due to the absence of that slight crepitation that accompanies the dilatation of the air-cells of the lungs, and the idea of a drier sound is suggested to us. It is strong in most parts of the neck. When the texture of the lungs becomes indurated or condensed from any cause, such as pleuritic effusion or the changes occasioned by a severe peripneumony or hymophysis, the vesicular respiration having then disappeared, or being much lessened, we can frequently perceive distinctly the bronchial respiration, not only in the large, but even in the small ramifications of the bronchi. The cause of this bronchial respiration appears to me very obvious; in fact, when the air is prevented from penetrating the cells this is the only kind of respiration that can exist, and is louder and more distinct in proportion as the lung is more condensed and thereby becomes a better conductor of sound."

Dance, a French authority of later date, adopts virtually the views of Laennec, and states in the *Dictionnaire de Médecine, ou Répertoire Générale des Sciences Médicales*, of 1833, that bronchial breathing is present when the air passes through the bronchial tubes without reaching the pulmonary cells. It produces in the ear a sensation of columns of air winding in the tubes of a certain caliber, without the sound of vesicular expansion; sometimes the sound is so intense as to make it seem that the patient's breath is passing through the stethoscope instead of through the bronchial passages.

Skoda thought that the tubular breathing was the transmitted laryngeal sound intensified or otherwise altered through what he called consonance; but he does not use this word in its ordinary acoustic sense, but explains that he applies it with the compound meaning of consonance and resonance, applying the principles of the sounding-board to obtain the intensity that he suggests. He does not make his views clear, except so far as the principle is concerned. The following is a translation of what is written in his *Abhandlung über Perkussion und Auskultation:* Bronchial breathing can be higher, stronger, deeper, or weaker, or even just as high and as strong as laryngeal breathing, and is due to consonance in sound in the upper and lower portions of the air-passages; the difference in volume and pitch depends on the condition of the inner lining of the air-passages in admitting of the production of the consonant sounds.

The most elaborate treatment of this subject that has come to my notice is found in Flint on the *Respiratory Organs*. Here Austin Flint devotes considerable space to this subject, and concludes by regarding bronchial respiration as "consisting of transmitted sounds that are produced within the trachea and primary bronchi, and probably also within the subdivisions of the latter, and are conducted by the air in the tubes and the consolidated lung to the ear of the auscultator. In what proportion they are due to the trachea and the larger bronchi exterior to the lungs, and to what extent sounds generated within the pulmonary bronchial subdivisions may be combined, are points not easily determined."

Flint certainly had an analytic mind, and his description is the most satisfactory. More modern writers adopt this view without notable modification. Guttman devotes fair consideration to the opinions of others, but expresses his views as follows: "The bronchial respiratory murmur heard in disease is nothing more than the laryngeal sound carried with scarcely diminished intensity through consolidated

[1] Read at the meeting of the Association of American Physicians in Washington, May 24, 25, 26, 1892.

lung-tissue." The views of R. C. M. Page and Vierordt are virtually the same. So also are those of S. S. Burt, excepting that the latter speaks of the sound as being transmitted through the bronchial tubes as through a speaking-tube, directly to the surface and ear of the auscultator. It will be observed that there is no great variety of opinion, and, without quoting at greater length, authorities are not fully satisfied with their own explanations, for they quite universally acknowledge differences of pitch over different regions in the same individual, and even contrast the laryngeal and tubular pitch, pointing out differences that all will concede could not exist if the source of the sound were the same, for pitch cannot be altered by the medium of transmission, and, as Dr. Flint says, "there are circumstances which give rise to variations in pitch which we do not understand, and that the sounds generated within the trachea and bronchi as in conditions of health, will not suffice to explain the intensification of sound which sometimes characterizes bronchial respiration in disease, nor the disparity in pitch which is observed." He further concludes that "other physical influences are doubtless involved which are not as yet satisfactorily explained."

Dr. J. Bloodgood, of Chicago, published an article on this subject in 1860 which has not received the consideration that it deserves, and my attention was only called to it within the past few days. In this article it is claimed that hepatization is not necessary for the production of tubular breathing and that the normal lung-tissue offers a good medium for conducting sound, as demonstrated by the clearness with which sibilant râles are heard when the parenchyma is normal; that when a bronchus becomes temporarily blocked by viscid mucus a clear tubular sound is at once detected, and this disappears when the secretion is coughed up; during the time it is heard the lungs are normal. Dr. Bloodgood argues from this that the air in its passage downward is diverted into many tubes the aggregate capacity of which is much greater than that of the trachea and bronchi; that it therefore rushes more and more slowly the more deeply it penetrates; that should a small bronchus become plugged at a little distance from its origin, or lead to cells filled with inflammatory product, it would furnish a cavity analogous to the Pandean pipe, and yield a tone determined by its size; that if it were located high up in the lungs, where the air has the greatest velocity, it would be intense, but if located in the lower lobes the sound would not be induced, or if present the intensity would be diminished. His argument is based upon false anatomic grounds, and he does not accord the transmitted laryngo-tracheal sound its place.

I began, about three years ago, a line of work and experimentation having the great charm called original work, which always acts as a wholesome spur, and after eighteen months of time it developed most successful results; but in that time I also made the discovery that my undertaking was not new, though I had succeeded without the knowledge that the ground had already been staked out by others. The work referred to is the making of casts of the air passages, and for that purpose I used an alloy composed of—tin, 4 parts, lead 8, bismuth 15, and cadmium 3. This alloy softens at 60° Centigrade, and fuses at 65°.

I do not know how my castings may compare with those made by others whose opportunities may have been better than mine, and who may have purused their work for a longer period than I did, for I have never seen any of the kind; my object is only to illustrate the basis of the explanation here advanced as to the causes that contribute to the production of the sound that we all term tubular or bronchial breathing. The castings are made from healthy lungs. These should be procured as soon after death as possible, and the cast is formed by pouring the alloy of low fusion into the trachea and allowing it to penetrate as far as possible into the tubes and vesicles before it chills and consolidates. It hardens almost immediately into a solder-like form, and the lung is then macerated in caustic soda, and eaten off, leaving the casting, representing what must be the exact caliber and shape of the air-passages, as far as the metal has penetrated, without burning or destroying the pulmonary tissue. I need not remind you that success does not attend each attempt, that the degree of heat, the pressure and the presence of moisture will modify the result and act as factors in the frequent failures, and determine the degree of success. In most instances castings of the larger bronchial tubes were obtained; in some, of the most minute tubular subdivisions; and, in a few, of the surrounding vesicles.

Whenever the vesicular castings were obtained the tubes were of course hidden from view. The castings were also not complete throughout the lung, and were often unavoidably broken off in the preparation, even by their own weight. Human lungs do not prove good specimens unless procured from subjects dying from hemorrhage and after a short illness, as the mucus always present debars the possibility of a perfect cast. The preparations were made from adult and infant human lungs, and the lungs of sheep, calves, dogs and rabbits. In many cases the alloy was poured into the trachea while the lungs were still *in situ*.

It is not within the province of this paper to discuss the anatomy of the lungs or to point out the errors that exist in some of our best descriptive Anatomies; but I particularly invite attention to the

method of division or branching of the bronchial tubes, which quite uniformly takes place at about the same angle, and uniformly by bifurcation, and that the air only reaches the air-cells after passing through a long route and varying in its course at the different points of bifurcation. Furthermore, at these points the bronchial tube possesses a sharp edge, which acts as a prow to cut the column of air at the bifurcation. This cutting edge is described in Sappey's *Descriptive Anatomy*, and he says that on a level with each division one sees in the cavity of the bronchial tubes a spur or prow to cut the column of inspired air. If the bronchi are given off at an acute angle this spur is very pronounced and very sharp. In collapsed lungs the bronchi are naturally much diminished in size, and this cutting edge is not very apparent, as it is not thrown out in relief; but in consolidated lungs, as in pneumonia, it is readily seen. I am confident that bronchial breathing is a mixed sound, composed of laryngo-tracheal and cavernous elements, the laryngo-tracheal sound being transmitted through the bronchial tubes by the air in their cavities, and thence communicated to the consolidated or compressed lung, to the chest-wall, and heard by the auscultator, diminished in intensity according to the lack of transmitting power of the different media through which it has to pass; that added to this sound in proportions differing under different circumstances, but often predominating in volume, is a *tubular blow* that is produced by the air rushing over the open and cavernous mouth of a patulous bronchus that leads to a lung not receiving its quantum of inrushing air.

Now, bearing in mind the cavities represented by these bronchial tubes, either of the first, second or third magnitude, the air-cutting edge referred to by Sappey, at the point of bifurcation, I believe we have the explanation needed for variations in pitch, as well as one of the contributing elements in inducing tubular breathing, and, perchance, the same tubular blow will be induced, whether the air is passing in or out of the lungs.

This point can be demonstrated by five figures of a purely conventional character, to illustrate how tubular breathing can be produced in the higher grades of pneumonia with consolidation; in pleurisy, with effusion, when the lung is in contact with the chest-wall; in necrosis, with a cavity; and how, when produced, it could not be heard in cases of effusion, if fluid intervened between the lung and the chest-wall. In all of these cases it is apparent that over areas in which tubular breathing is heard there is diminished or suppressed vesicular expansion. Under these circumstances it can hardly be questioned that, in order to reach other portions of the lungs, the air rushes by and over the bronchus leading to the diseased portion, to fill the air-vesicles that do expand, and that at the point of departure the cutting edge described by Sappey must produce a reverberation, engendering a sound analogous to that which would be produced by blowing over a test-tube; and its pitch will depend upon the length and caliber of this bronchus; this is the additional sound that, for lack of a better term, I have called the *bronchial blow*. If the rush of air to other parts of the lungs is rapid, the intensity of this sound will be augmented. If the size of the tube be small and shallow, its pitch will be raised; if large and deep, the pitch relatively lowered; but in any case, higher than a laryngo-tracheal sound, except in conditions of disease of the larynx, in which case its pitch might be raised much above the normal. When this sound is intense, as we find it in the rapid breathing of acute pneumonia, or extensive effusion, with the lung pressed or bound to the thoracic wall, it contributes largely to the sounds heard, thus raising the pitch and augmenting the intensity. Should rapid breathing subside in the cases named, or should secretion obstruct the mouth of the tube, or fill its cavity, then the intensity of this element would diminish, or the sound entirely disappear. The pitch of this blowing sound is determined, as has just been stated, by acoustic laws and depends upon the length of the bronchus and its caliber at its point of departure. The principle is susceptible of ready demonstration, with apparatus to be found in any of our offices. Blowing over a small test-tube will yield a sound of a certain pitch; on filling the tube partially with water, the pitch will be raised; a long, narrow tube will yield a low-pitched sound; a flask may be treated in the same way to illustrate the reverberation in a cavity. This experiment may serve to explain how, after a short lapse of time, both pitch and intensity of sound may be altered in conditions of consolidation by the presence of secretion in the tubes. I would further offer as an explanation of the exaggeration of the tubular element heard over cavities, particularly when they are near the surface, that the intensity is very much augmented by the proximity of the sound to the ear of the auscultator, and this rule applies equally to all physical sounds, and the more remote from the point of its production, the less audible it becomes; it is for this reason that sounds are sometimes limited to very small areas, particularly when the medium of transmission is poor. Again, sounds produced externally to the larynx cannot be heard with distinctness, and those which are most distinctly heard are produced at the periphery of the air-passages, or near the ear of the auscultator; labial sounds, such as chirping and whistling, are only heard as transmitted by the

external air; they are never intense, whereas any artificial means that produce a rush of air in the respiratory tract nearer the ear are markedly exaggerated, as, for instance, the expiratory "puffs," produced in this way; whisperings are intensified in like manner; the intensity of sound at different periods of respiration depends upon the same law. I do not think it would be possible to state what proportion of the sound is attributable to the different elements that go to make it up, for I am convinced that the proportion varies notably with different degrees of consolidation and under varying conditions, the discussion of which would be foreign to my purpose here. It seems to me that the reason why this explanation has not been offered before is because the size of the tubes has been very much underrated by those who are in the habit of making physical examinations; commonly when examined the lungs are collapsed and the bronchi are diminished in size, but the castings show that there are fully sixty tubes in the human lung capable of inducing a bronchial, blowing sound, while several bronchial casts in distended lungs have a diameter of about half an inch in the clear; these latter would certainly yield a large volume of sound.

Before closing I would not be understood as saying that the larynx does not play a rôle, and a very important one, in determining the pitch and quality of bronchial breathing, for I have experimented upon some of the lower animals, inducing pulmonary consolidation, and with an opening into the trachea I have been able to cut off the laryngeal sound at will; from this experiment, although it was not complete, for I found it difficult to produce pneumonia in a dog at will, I was convinced that the larynx, as well as the trachea and the *bronchial blow*, are the three elements that, in the aggregate, induce the sound that has been the subject of this paper.

SYPHILIS OF THE LINGUAL TONSIL.[1]

BY JAMES E. NEWCOMB, M.D.,
ATTENDING LARYNGOLOGIST, DEMILT DISPENSARY; ASSISTANT IN THE ROOSEVELT OUT-PATIENT (THROAT) DEPARTMENT, NEW YORK CITY.

ALTHOUGH the past decade has witnessed marvellous progress in every department of that branch of medical science that specially interests the members of this Section, in none, perhaps, has greater interest been felt than in the one that concerns the pathology and treatment of the various conditions that beset the adenoid tissue of the mouth and nasopharynx.

The introduction, by Waldeyer, of the term "tonsillar ring" into medical literature has led to a more accurate understanding of the relation of the various adenoid deposits to each other, both in structure and in function. Nor, moreover, is this term merely a fanciful one. There is almost a circular continuity of adenoid tissue from the nasopharyngeal vault to the tubal deposits, to those on the posterior surface of the soft palate, to the faucial tonsils, and to those at the base of the tongue.

Modern histologists have greatly differed as to what constitutes a typical tonsil. It seems to me that the recent paper of Harrison Allen (1) is at present the best exposition of the subject. According to this writer, a tonsil is essentially an association of diverticula developed from the epithelial layer of the mucous membrane. In the walls of these diverticula are grouped muciparous glands and lymph-follicles; and the mouths of the diverticula open in a uniform manner on the surface of the mass. The various tonsillar masses differ only in the arrangement of these anatomic units, so to speak. In the lingual or fourth tonsil they are single.

In spite of all we know regarding the structure of this tissue, however, we are still in the dark as to its physiology. Hingston Fox's theory (*Lancet*, 1888) of absorption has been discarded. Scanes Spicer's views as to their share in the blood formation (2), "nurseries for young leukocytes, planted by the waterside and drawing their sustenance from the streams nutrient," afford opportunity for pleasing phrases, but do not recognize certain obscure points in our knowledge. The fascinating doctrine of phagocytosis, advanced by Metschnikoff, caused many to think that the problem had been solved, but further investigations, carried on in a calmer frame of mind, have caused the profession to bring in the Scotch verdict of "not proven." Yet this doctrine is certainly worthy of consideration, for it fulfils, better perhaps than any other, the condition of a scientific theory, viz., it best explains observed phenomena. Hodenpyl, in a recent article, regards the functions of the tonsils as unknown.

The latest portion of the tonsillar ring to receive attention has been that localized thickening and broadening of the adenoid tissue at the base of the tongue. That we call the fourth or lingual tonsil. It is situated behind the circumvallate papillæ, and extends a varying distance toward the anterior surface of the epiglottis. It consists of closed follicles surrounded by irregular masses of adenoid tisse, the whole bound up in connective tissue. Our great advance in knowledge has come in the realization of this fact: that we have here, both in structure and in function, a tonsil, modified, it is true, by its situation, but subject to all of the mutations of tonsillar life. Stoerck, in 1877, first called attention to the trouble that its enlargement may produce by

[1] A paper read before the Laryngological Section of the New York Academy of Medicine, April 27, 1892.

irritation of the epiglottis. Since then many observers have reported various reflex neuroses arising therefrom. Curtiss has shown its effects upon the singing voice; Joal (3), how it may cause esophageal spasm and be a factor in globus hystericus; Heyman, Michael, Bentz, Rice, Swain, and others, have discussed the general question. Attention has also recently been called by Ruaulb (4) to the fact that we may have a peri-amygdalar cellulitis here, as in the fauces. He reports five cases of this affection: once in the median line, three times to the right, and once to the left. It is worthy of note that tonsillar hypertrophy here is generally confined to the middle period of life, while in faucial and retronasal situations the hypertrophy is characteristic of adolescence.

Furthermore, we have learned that the fourth tonsil is not merely a servile imitator of those pathologic processes that precede it in other segments of the tonsillar ring. It may present conditions entirely independent of those of its neighbors. These may be involved while it escapes. Natier (5) has noted that in syphilis of the faucial tonsils we may have a thickening of the ary-epiglottidean folds, with a tumefaction of the epiglottis by an abundant vascularization, while the fourth tonsil escapes intact. Schaede (6) has seen enlargement of the latter, while the other adenoid deposits have been in an atrophic condition.

The lingual tonsil, however, can lay claim to being the site at which diathetic influences may frequently localize themselves. Little attention has, until recently, been directed to its relation to the syphilitic virus. That such a relation exists is beyond dispute. We have heard much about chancre of the lip, of the anterior part of the tongue, and of the faucial tonsils with their pillars. From the sheltered position of the lingual tonsil, it can rarely, if ever, be the seat of primary infection. In fact, in a careful review of the literature, no such case has come to my notice. It is often the seat of secondary trouble, more rarely of the gummatous deposit, with its subsequent breaking down. This would be a logical deduction from the law of identity in structure and function, and one corroborated by clinical experience. Yet it is somewhat remarkable that the syphilographers, who go into such details in regard to specific lesions of other parts of the mouth, should have passed over the matter in silence, especially as now over thirty years have elapsed since the existence of true lingual chancre was demonstrated by Le Gendre. The causes of this condition and the circumstances that determine the localization of the lesion are, as far as we know, referable entirely to various forms of irritation. It is more common in men, and generally in young adult life. It is more common in those addicted to excesses in tobacco and alcohol; also, in those whose occupations require prolonged straining of the vocal organs. Further than this, the lesion offers no exception to the general rules of syphilis.

The condition is frequently overlooked because the symptoms do not differ from those observed when the pharyngeal walls bear the brunt of the trouble. When the localization is at the base of the tongue, in the median line, there is the sensation as of a foreign body. When it is confined, as it sometimes is, to the lateral portions, the function of the pharynx in deglutition causes more or less painful swallowing, the pain radiating toward the ears. The voice is frequently husky, and becomes quickly fatigued. Cough is frequently present, and not rarely asthmatic breathing. In other words, the syphilitic lesion occasions no other distinctive symptoms than may arise from simple hypertrophy.

It is in the pathologic appearances, perhaps, that the greatest interest centers. These may manifest themselves either in the median line or on either side thereof. Two different pictures present themselves—as best described by Moure and Raulin: (7)
1. Nipple-shaped protuberances, grayish-red in color, and separated by furrows. Their summits are ulcerated and crowned with the typical mucous plaque, clean-cut, and clearly differentiated from the surrounding surface. Each protuberance corresponds to a group of closed and inflamed follicles. The neighboring tissues are not at all involved.
2. There is at times a single tumefaction, median or lateral; a compact mass with slightly projecting swellings, the top of each of which is covered with mucous plaques, varying in size, diffuse and generally ulcerated. The whole mass is of ovoid or spherical shape, and the area involved is much greater than in the first variety. Here, while the closed follicles are infiltrated, the tissue between them is also infiltrated, and this interstitial infiltration is what goes to make up the mass. The epithelial layer of the mucous membrane and the submucous connective tissue both participate in the morbid process. There is not only a folliculitis, as in the first variety, but a peri-folliculitis as well—a folliculo-interstitial process. The transformation of the first type into the second is very rare. Of course, we must bear in mind that in any case the exact picture varies according to the normal distribution of the follicles and their size before infiltration, which in turn depends upon the preëxistence of simple hypertrophy.

The clinical history of a case that has recently come under observation, is as follows:

W. D., a colored man, thirty-one years old, was first seen in the Roosevelt Out-patient Department (in the service of Dr. Jonathan Wright), January 23, 1892. The man was a porter, stout, and of

rugged physique. His family history was good. He was a moderate drinker of malt liquors, and had used tobacco to excess. Last fall he had a slight attack of rheumatism, that did not compel him to give up work. In September, 1891, he had the initial lesion of syphilis. No alopecia or rash followed, but in December (about six weeks before coming under observation) he began to complain of sore-throat, with pain in swallowing. Examination revealed a normal nose. The faucial tonsils were swollen, and their surface more or less convoluted. The inside of the cheeks was sprinkled with mucous plaques, and the anterior surface of the tongue as well. A few superficial ulcerations existed in the naso-pharynx. At the base of the tongue, on either side of the median line, were situated lesions of the first variety, previously described.

Labit ([8]) has recently described a somewhat similar case. His patient was a male, twenty-nine years old, who had contracted syphilis six months before. No rash had been observed. Three months before the man was first seen he had begun to have painful spots in the mouth, with hoarseness and difficulty in swallowing. There was a general redness of the faucial tonsils and of the palatine vaults. The latter showed whitish patches, elliptical in shape, with uneven edges. There was an erythematous redness of the larynx, with slight inflammation of the ary-epiglottidean folds and vocal bands. In the region of the lingual tonsil the follicles appeared as projecting nipples, red, varying in size and separated by furrows of varying depth. The summits of some of these projections were covered with grayish ulcerations, contrasting strongly with the surrounding redness.

The tertiary lesions are more uncommon. Natier([5]), writing in 1890, had been able to find the records of only fifteen cases in French literature. The diagnosis of this condition is difficult before the appearance of disintegration, and yet of the utmost importance, because the ulcerations may extend deeply and reach important bloodvessels.

A few words may be said concerning the differential diagnosis. This, as in doubtful specific cases, must be made from the history, the local appearance, and other evidences in neighboring parts. Schumacher ([9]) has called attention to one clinical manifestation that might give rise to some confusion. It is a local appearance met with, independently of mercurial stomatitis, in the pharynx of those patients who are being treated by inunctions. It begins among the circumvallate papillæ, and spreads backward to the epiglottis, attacking especially the edges of the pharyngeal and epiglottidean mucous membrane, passing down at times to the entrance of the larynx, seldom to the posterior laryngeal wall. At first there is only a slight dulness of color, but in a few days there are visible snow-white deposits, from one-half to one centimeter in circumference, surrounded by a zone of intense redness. If the condition be severe, the cervical and submaxillary glands may swell. Such manifestations generally precede the cutaneous eruption.

Concerning the early diagnosis of the gumma, we are aided by the induration of the surrounding area, the center of which will, if the evolution of the deposit be not checked, eventually support the deep cone-shaped ulcer characteristic of the fully-developed lesion. A suspicious sign is a slight thickening of the palate and the same side of the uvula. The absence of adenopathy is negative evidence. Its presence also does not greatly help us, because a unilateral glandular enlargement is characteristic of several affections. Moreover, carcinoma, chronic abscess, and diphtheria may all be attended with the radiating pains already alluded to. Here, as elsewhere, the grouping of features must decide the diagnosis.

Concerning the treatment of this condition, we are fortunately in a position to do much. The internal medication with the various mercurials generally yields prompt and satisfactory results. For local relief, we may at first need sedative applications. Natier has suggested a spray of potassic bromide with cocaine, in cherry-laurel water; Moure and Raulin, a gargle of Sydenham's laudanum in glycerin. For an alterative effect probably nothing exceeds in efficacy Mandl's solution of iodine, potassium iodide, and carbolic acid in glycerin. There is some danger in too irritant applications, as the epiglottis and larynx might be injured. Spasm of the glottis, and even edema, are not mere fanciful dangers. In the acute stage, the applications of dilute acid nitrate of mercury stimulate to healthy action. This, in my own case, with a sublimate gargle and mixed treatment, led to a cure in about five weeks. For inveterate cases, light applications of the cautery have served as a useful adjunct to other treatment.

SOME PRACTICAL POINTS IN REGARD TO EYE-STRAIN.[1]

BY R. O. COTTER, M.D.,
OF MACON, GA.

MY reason—I will not say apology—for calling attention to this rather hackneyed subject is

[1] Read before the Georgia State Medical Association, April 21, 1892.

because in my daily work as an oculist I am constantly impressed with the observation that the vast majority of general practitioners overlook the easily substantiated fact that such a multitude of morbid reflex neuroses are brought about by eye-strain—that is to say, uncorrected errors of refraction. I refer especially to hyperopia and hyperopic astigmatism. As to myopia (near-sightedness), I have little to say of it, as it is rarely accompanied by headache and eye-strain. Myopes complain simply of not being able to see well enough at a distance.

Headache is by far the most common accompaniment of hyperopia and astigmatism. These headaches are most common in the temples, the frontal region, and vertex. They frequently appear to be what are known as sick or bilious headaches, and are in any case truly distressing in character. Among the other symptoms are a congested or inflamed conjunctiva, blepharitis, styes, chalazia, frequently an annoying and uncontrollable twitching of the eyelids, aching of the eyeballs, etc.

There is no doubt that chorea is often developed in children as a result of this same cause. There is, also, no doubt that in persons of neurotic temperament, indigestion, nervous dyspepsia, insomnia, and more or less complete physical prostration, are brought on simply from uncorrected eye-strain. There are plenty of these cases on record. I verily believe that there are very many helpless opium-habitués and inmates of insane-asylums whose unbearable suffering from this very cause was the cause of their first step in their downward career.

The incredulous general practitioner who has not yet become impressed with the truth in this matter will smile at what he not unnaturally believes are the vagaries of the hobby-riding oculist. Gentlemen, while I know that unfortunately there are riders of hobbies among oculists as there are in all specialties, let me remind you that the demonstration and correction of ametropia comes a little nearer being an exact science than any other branch of our profession. As for my own work in this line, I think it has been conscientious and painstaking. My books are open to you at any time; my patients are accessible to many of you throughout this section. They, and the results accomplished, can speak for themselves. I will try to illustrate by reciting two or three cases:

CASE I.—Mrs. A., a married lady, aged twenty-seven years, of neurotic temperament, has no organic disease, and for several years has been an almost constant sufferer from the most horrible headaches. Any attempt to read or sew would result in her having to go to bed with a sick-headache. Even when she went out shopping, a terrible headache was certain to follow. The poor woman had, fortunately, successfully fought against taking opium, but she afterward told me that she had almost concluded to ease her torture by resorting to morphine. She had unmistakably injured her system by taking great quantities of antipyrin, phenacetin, etc., and this was largely by physicians' directions. She became wasted and yellow, and was fast losing all hope of relief. Her very life was becoming rapidly blighted.

Now, strange to say, of the six reputable physicians who had treated her for her headaches, etc., five of them were men who would have promptly referred a case of granulated lids, iritis, or any other manifest eye-trouble to the oculist for special treatment, but only one of these six, and she a woman physician just out of college, seemed to suspect the real origin and cause of this patient's trouble, and she sent her to me, the patient protesting all the time that "she had no faith in an eye-doctor curing her headaches, because she had no eye-trouble—could see well enough," she thought, and her eyes were not at all inflamed. I found that her vision was, R. E. 20/LXX, and L. E. 20/XL, of the normal acuity. With a four-grain solution of atropine, dropped into her eyes night and morning, I found R. E. = 20/CC, L. E. = 20/LXX. From the very hour, by the way, in which I dilated her pupils, she got relief from her headache (so long as the accommodative paralysis lasted), and she informed me next morning that she had, for the first time in months, enjoyed a night's rest free of headache.

By way of digression, let me say, that it is a very good rule, when you encounter severe and intractable headaches in young persons (say persons under forty), to drop a few drops of a four-grain-to-the-ounce solution of atropine in their eyes, and very generally, not invariably however, if their headache is relieved, you can pretty safely put it down as a case of refractive error.

To return to my patient: I found the following remarkable condition of mixed astigmatism:

R. E. + 1.50 D, cyl. axis 90° ⊖ — 1 D, cyl. ax. 180°.
L. E. + 1 D, cyl. axis 90° ⊖ — .50, cyl. ax. 50.°

This may truly be called a diabolical error of refraction.

I prescribed these glasses, and knowing that she would soon become disgusted with the attempts to use them with undilated pupils, I began with dilated pupils, and predicted confidently that they would give her great relief, though I candidly told her that it might require considerable time to get her over her headache habit—for there undoubtedly is a headache habit, so to speak, a condition of periodic or constant headache that does become habitual. For several weeks thereafter, when she would become discouraged on the attempt to use her glasses, I would dilate her pupils. It required all my tact to keep her using them, but now, after many months have elapsed, I can truthfully say that the correction of this lady's refractive error has made life a very different sort of existence to her, and has changed her suffering condition to one of happiness and joy. She is free from her terrible

headaches, and has gained flesh and strength. Nothing else was done for her but the correction of her eye-trouble. She finds most comfort in the constant use of her glasses, and her vision with them now is, R. and L., 20/XX.

While such a peculiar astigmatism as hers is very rare, I could recite the cases of many patients, even with very slight degrees of astigmatism and hyperopia, who suffer with the most terrible headaches in consequence, and very many of these patients have normal vision. I myself have more than normal acuteness of vision, it frequently being as good as 20/XII, and yet I have an astigmatism of + .75 D, ax. 90°, and a hyperopia of + .75 D. If it were reduced to a question of simple comfort, I would prefer to give up my shoes or hat rather than my glasses. I said that we do not usually find eye-strain in persons over forty-five, for the reason that nature has brought on a change or loss of function in the ciliary muscle, so that they can no longer overexert it; yet, sometimes we do find that in such patients there is eye-strain or asthenopia.

CASE II.—Mrs. ——, aged fifty, of Boston, had been fitted with the glasses ordinarily proper for the presbyopia usual to one of her age, yet she has for many years had great trouble upon any attempt to read or sew. She suffered severely with eye-ache, styes, inflamed lids, etc. While spending the winter in this State she was advised to consult me. As I could find no other ocular trouble, I made a careful ocular test of her refraction. At her age, of course, I did not use a mydriatic. Her vision was 20/XX. I found that her Boston oculist, who was a man of reputation, had overlooked or failed to correct an error of one-quarter of a diopter of hyperopic astigmatism, which my test plainly showed. I prescribed glasses: + 2 D ⊃ .25 cyl. ax. 90°, for close use, and soon had the happiest results follow their use. She rapidly recovered from her eyeaches and inflamed lids, and now uses her eyes as much as she chooses. Bear in mind that this lady had the slightest degree of astigmatism that we ever encounter. I have no doubt that in prescribing glasses for presbyopia all occasionally commit the same inadvertence which this lady's former oculist did.

CASE III.—A boy, seven years old, had been growing more cross-eyed for nearly a year, but as it was of the alternating variety and not firmly established in either eye, his parents consulted me about a nervous twitching of his limbs, neck, etc. (chorea), rather than for eye-trouble. His vision was below normal, but this had not been previously noticed.

When I proposed to undertake the correction of his trouble by the use of glasses, they objected very vigorously to his using them, unless I could make the ridiculous, but very frequently desired, promise that their son would soon be able to leave off the use of glasses. They were willing, though, that I should perform an operation for the strabismus which, by the way, was now about two and a half lines. Of course, I refused to touch the case at all under these circumstances. I think they brought the boy to me half a dozen times during the year, asking me to operate on him. Finally, seeing that I was bound to have my way in the matter, they consented to an examination of the boy's refraction. His vision was:

R. = 20/XL. L. = 20/L.
Under atropine: R. = 10/CC. L. = 10/CC.
With + 6 D: R. and L. 20/XX, or normal.

I prescribed this full correction, and by keeping his pupils under atropine for two or three weeks he experienced no trouble in wearing his glasses. His strabismus and chorea disappeared at once, and have not returned after two years. The boy has been at school ever since.

I never cut a muscle when I can do what is necessary without it. This I consider conservative ophthalmology. Of course, when the squint has become firmly established, we have (usually) to operate as well as correct the refractive error.

My observation is that even in children when the error is as much or more than + 3 D, it is best to try to make them wear a fully correcting glass constantly. When the error in young persons is less than 2 D, I wish to state that I do not now so frequently prescribe a fully correcting glass for close use as I formerly did.

I shall not weary you with detailing accounts of cases showing the very long train of morbid nervous conditions brought about by uncorrected refractive errors. All these have been clearly proved to exist by faithful and painstaking workers in ophthalmology. As for myself, I assure you that I do not prescribe glasses for every case of small refractive error that I find. Many of these require general systemic treatment and toning up, and I send them back to their family physicians. Many others simply need a rest, or to stop abusing their eyes; and as I well know if given glasses they would simply continue to overtax their eyes, I generally refuse to prescribe glasses. I have good reason to suspect that there has of late been too much hobby-riding by some in the way of useless muscle-cutting for heterophoria. My observation of several years convinces me that eye-strain is not so much caused by a lack of equilibrium of the external muscles of the eyeball (heterophoria). Neither do my patients require prisms so frequently as employed by others. I am thoroughly convinced that the very great majority of cases, of eye-strain that I see are caused by ciliary strain, which is of course due, in the cases I speak of, to ametropia. I have very frequently found persons wearing prisms who were unrelieved thereby, and upon my searching very carefully I could find no occasion whatever for them, and have relieved many of them by leaving off the prisms and

correcting their refractive error. I am always willing and ready to compare results with the muscle-cutting and prism enthusiasts.

A word about mydriatics in refractive work. I believe I have thoroughly tested the comparative merits of atropine and homatropine, and while admitting the discomfort and inconvenience caused the patient by atropine, I must still say that homatropine is so very frequently unreliable, that in cases in which it fails to give accommodative paralysis I very often have to resort to atropine. In young persons under thirty I always, if possible, use atropine. Of all methods of exhibiting homatropine that I have used I consider the gelatin discs advised by Dr. Casey A. Wood, of Chicago, by far the best. As to the practice of attempting to correct these refractive errors simply with the ophthalmoscope, *i. e.*, without a mydriatic, I had as lief argue with a man who preaches against the value of vaccination as with a man that asserts that refraction work can thus be properly done.

The correction of refractive errors, gentlemen, is the most prominent, and by far the most scientific, part of an oculist's work, and I assure you that too many general practitioners overlook many of these cases. One meets with a hundred of these sufferers to one of cataract.

INTESTINAL LESIONS IN ABDOMINAL AND PELVIC SURGERY.[1]

BY JOSEPH PRICE, M.D.,
OF PHILADELPHIA.

IT is not my purpose to consider in detail all of the complexities and manifold relations of abdominal and pelvic surgery. I only desire to indicate the part that intestinal lesions play in making the pathology of abdominal and pelvic disorders complex, and afterward to consider the best way of dealing with the intestinal complications for the good of the patient and the comfort of the surgeon.

In order to appreciate the part that intestinal lesions play in obscuring the diagnosis and interfering with the surgical treatment, it is necessary to study the history of all pelvic pathologic growths, as well as of suppurative and inflammatory products found in the pelvis. Complications involving the hollow viscera during the progress of the growth or formation of these tumors and products furnish the chief danger experienced in the surgical relief of patients so suffering. It is rare that any suppurative process is ended without some intestinal complication in either the pelvis or abdomen. In the presence of such processes, universal adhesions to all surrounding organs is the rule. This is true of purulent deposits in the tubes, abscess of the ovary, and in the dermoid cyst, whether large or small.

The appendix, in my experience, plays no small part in complicating ovarian and tubal trouble on the right side; when this is the case this organ must be removed, though primarily it may not have entered into the consideration of the surgeon at all. In more than one instance, operations in which the appendix has been removed have been instituted for some condition not associated with the appendix.

It is plain that in order to be successful in the treatment of pelvic and abdominal troubles a comparative knowledge of the complications must be had. Aside from conditions brought about by purely pathologic processes, post-operative complications, due for the most part to hasty, ill-advised work, or unfinished operations, are at the bottom of a good deal of surgical complication that would not otherwise exist. Such operations are the worst that surgery has to deal with, because they involve both new and old inflammations, together with the effacement of anatomic landmarks that would otherwise exist. Nevertheless, there is much to be learned from these operations, just as we have learned much from the pioneer attempts of the earlier gynecologists, and a dexterity acquired in manipulating the complicated cases is of infinite value in the simpler ones.

In the same category may be placed complications due to failure to drain, and the use of irritating solutions. If we do not drain products likely to go on to organization, or if we use fluids that encourage inflammatory peritoneal adhesions, it is evident that we are at once on both horns of a dilemma, and the patient will be prodded from two quarters. Meddlesome interference with what would otherwise be natural drainage, by the introduction of quantities of gauze into the pelvis, must of necessity produce adhesions. The less the peritoneum is finally meddled with after the completion of an operation, so much more surely will there be an absence of damaging adhesions. What is required here, as in all work from which good results are to be expected, is to rely on logical procedures scientifically applied. Hop-skip-and-jump methods, while they are exciting and acrobatic, cannot be trusted to save patients.

Going back to a former assertion that the history of these growths is important in preventing the accidents of operation, in no other condition is this truer than in ectopic pregnancy. Here, if we hold in mind the almost inevitable complication of a bleeding tube, we are able at once to control the bleeding, and without loss of time in searching for the point of leakage, go at once to it and so save the life of the patient. In all bowel-troubles, in any or all of these conditions, rapid and accurate repair is of the most importance. That is not surgery at all

[1] Read in the Section on Surgery and Anatomy, American Medical Association, June, 1892.

that takes chances and leaves to Nature, so-called, what is only the surrender of ignorance or inefficiency. Inflammatory adhesions do not confine themselves to the intestines, but extend to all organs, hollow and solid. Such being the case, it is evident that whatever anatomic peculiarity each organ possesses is a necessary part of our surgical equipment if we hope to deal successfully with its lesions. In dealing, therefore, with the adhesions of the various organs, our anatomic, physiologic, and pathologic knowledge is put to the test, both as to what may be sacrificed and what must be saved, and toward which line the path of safety reaches. In this connection it is at once apparent that the mere theorist, or theoretic operator, or lecturer, may have little conception or idea of the operative requirements of a given case, and is, therefore, in no position either to advise or to perform an operation. The requirements of success are both scientific and artistic, both theoretic and practical. In no point is this axiom so apparent as in the method of dealing with adhesions, which so often fuse all adjoining structures into what seems a conglomerate mass.

Mere theory, and the theorist in abdominal and pelvic surgery, would say, Separate the parts and organs with the knife; while experience and experienced operators say, Use only the finger-tip, seeking a line of cleavage, and thereby avoid the danger of wounding tissues that must be separated. The methods of general surgery here are not applicable to intestinal work. Such means can only be safely applied to post-mortem work. No violent methods are to be employed; gentle, persistent effort is alone the safe and successful means. Cultivated, delicate tactile sense, attained only by having a sharp wit at one's finger-ends, is the key to the situation. The refinement of feeling possible is only possible of conception after it has been attained.

The complication induced by removing adhesions is hemorrhage. This we must control, not by ligatures, unless exceptionally, but by packing, if necessary, and by flushings of the bleeding cavities with water as hot as can be employed without interference with or destruction of the vitality of the tissues. This expedient will frequently save patients otherwise doomed. More than one case so saved could be detailed. In advising this procedure I know that I am running counter to the views of the theorists, who see in it all manner of dangers, but practice does not sustain them, and the surgical advantage obtained by the hot-water flush is indisputable. This is especially true in patients exhausted from any cause whatever. Irrigation is then a real requirement after any operation incident to purulent or other inflammation in the pelvis or abdomen.

In all suppurative and inflammatory abdominal and pelvic disease, the line of treatment briefly should be as follows:

First remove the diseased organs; then carefully flush the parts free of débris; and lastly drain carefully, thereby assisting the economy to rid itself of accidentally retained shreds and clots. After the adhesions have all been overcome, careful examination of the hollow viscera is to be made, or, indeed it were a better practice, to examine all doubtful portions of intestine, and repair them as we proceed. They should be mended so as not to interfere with the integrity of the bowel in the performance of its functions. This is the rule in dealing with all other organs.

In contradistinction with the entire and careful removal of the diseased parts, we have so called conservative methods brought into bold relief—to their disadvantage. We are counselled to puncture and drain pus sacs *per vaginam*, in order to avoid infecting the peritoneum. This is another conflict between mere theory and practice. If pus-cavities, as we find them in the pelvis, were simple, and involved but a single organ—in fact, if they were something they are not—such treatment would be commendable; but if, as in the great majority of cases, the sac is only one of a number of complications, no one of which can be punctured away, we must concede that such expedients are not conservative, but only specious devices to escape depths in surgery through which their suggestors can neither swim nor wade, and hence they flounder in their despair, seizing this and that to lead them out of their perplexity.

A single illustration or two will suffice to show the deceptive nature of such tentative operations in so-called pelvic abscess. We know by wide experience that all abscess-formation in the pelvis is in the great majority of cases dependent upon tubal or ovarian inflammation, which is rarely uncomplicated, and in the majority of cases has involved intestine, often omentum; the bowel is often perforated; the bladder is not seldom implicated. We have seen too that the appendix is not seldom bound down in the almost universal adhesions. If now there is a lesion of the bladder through which pus is just ready to escape, or is escaping, simple puncture cannot undo the mischief, and the same is true if the appendix is involved, with tube and bowel. Granting that one pocket of pus can be emptied by puncture, this will not do away with the adhesions that are often the chief seat of pain, and are a constant menace to the patient by exposing her to the dangers of obstruction. The sequelæ of many of these cases treated by puncture and drainage is often a most mournful travesty upon surgery, as witness the histories given by the operators themselves.

In a discussion before the New York Obstetrical Society, and published in *The American Journal of Obstetrics* for March, 1892, Dr. Paul F. Mundé is quoted as saying that "during the last *few years* he had opened *forty* pelvic *abscesses through the abdomen, eighteen* through the *vagina*, and four through the abdominal wall and vagina at the same time. In several cases he had punctured the vaginal wall in order to secure thorough drainage, abdominal drainage not being sufficient. In three of these cases, while drawing the drainage-tube through from the vagina to the abdominal wound, the bladder was accidentally wounded."

Consider a total of sixty-two cases of accumulation of pus in the tubes and ovaries, due to occlusion and suppuration; that dilatation of the tubes in a majority of this group "attained the size of a breakfast sausage, a banana, or a closed fist." In this group the practical surgeon can understand that vast number of serious complications following, first, the delay, and, secondly, the palliative methods of so-called treatment. Early primary sections, with complete removal of pus-sacs, would result in a mortality of *nil*. A large number of the group referred to have gone into the hands of other men for treatment. Such cases are constantly coming to me; and, well knowing how much more complicated they are, I dread them. In somewhat the same line, Dr. Mundé says: "We have boils and abscesses in the cellular tissue of other parts of the body. Why should we not have them in the pelvis?" And again, in a recent publication: "The empty *sac*, *lined by pyogenic membrane*, may, for an unlimited time, go on pouring out pus." The comment I would make very brief: Boils and true abscesses are not empty sacs.

Again: "We will all admit that many cases of 'pelvic abscess' in former days were really adherent pyosalpinx. I have, doubtless, punctured many a one in past days, never dreaming that it was anything but an abscess in the pelvic cellular tissue. I know better now." The comment can here be made: No longer is it a boil or an abscess in the cellular tissue.

"One of the great problems in my experience," says Dr. Mundé, "has been the sinus that is liable to remain after opening the abscess. I am sorry to say that I know of no sure way to prevent or cure them as yet. I have enlarged the wound over and over again, scraped them, cauterized them, punctured through into the vagina, and run drainage-tubes through, hoping the opening would close from above downward, but all of no use. I have, I suppose, a dozen women walking about this city now who are wearing different sorts of drainage-tubes. I would like to have some gentleman tell me how I can prevent these sinuses in the first place, and, in the second place, how I can heal them up." In the interest of the patient, the best thing to do in such cases—in fact, in all cases in which we don't know how—is not to attempt to do the operation, but send the patient to someone who, first, understands the pathology; and, second, the surgery. To cure these sinuses, remove the remaining diseased tube and ovary. This will do away with the necessity of "walking around wearing drainage-tubes"—a very uncomfortable interference with locomotion.

A BRIEF SUMMARY OF THE CLINICAL HISTORY AND TREATMENT OF TWO THOUSAND AND TWELVE CASES OF ALCOHOLISM, OF WHICH EIGHTY-SEVEN WERE MANIACAL.[1]

BY THOS. S. LATIMER, M.D.,
OF BALTIMORE.

IN the spring of 1891, at a meeting of the Johns Hopkins Hospital Medical Society, I reported 958 cases of alcoholism occurring at the Baltimore City Jail, between April 11 and December 30, 1890, of which 40 cases were of *mania à potu*, with an average duration of mania of forty-eight hours.

In these cases no distinction was made between *mania à potu* and delirium tremens. They were simply cases of mania due to alcoholic excess, accompanied in most instances by hallucinations of abhorrent nature, with tremors, great feebleness, loss of appetite, vomiting in many cases, and inability to sleep. In the non-maniacal cases, all of the symptoms related were uniformly present (including tremor) except the mental disturbance. All were treated with potassium bromide; the maniacal cases with thirty-grain doses every two hours, and the non-manical with the same dose at intervals of four hours. No addition was made to this treatment, except in three or four cases in which ten drops of tincture of digitalis and five grains of ammonium carbonate at intervals of three hours were also given; all recovered.

Since reporting these I have had opportunity to observe in the same institution 1054 additional cases, of which 47 were maniacal. This report, therefore, may be said to be a brief history of the gross clinical features and treatment of 2012 cases of alcoholism, of which 87 were maniacal. No attempt is here made to discuss the pathology of alcoholism, or any of the symptoms, except those directly connected with the debauch in the habitual drinker. No reference is therefore made to symptoms presumably due to persistent hepatic, renal, or peripheral nerve-lesions.

Nearly all of these patients were arrested for

[1] Read at the Seventh Annual Meeting of the Association of American Physicians, held at Washington, May 24, 25, 26, 1892.

drunkenness and disorderly conduct. They were technically called "peace cases," to imply that they were arrested for breaking the peace. A majority of them were also what in the jail are called "regulars," from the regularity with which they were returned after very brief absence. Two noteworthy facts are contained in the foregoing statement:

1. The cases were all drunk when arrested, and many of them had not yet become sober when brought to jail.

2. They were cases of almost continuous drunkenness, culminating at short intervals in a severe debauch, leading to some act of violence, or to a condition of drunken stupor, in which they were picked up on the streets quite helpless and almost or quite unconscious.

It was also quite common for my hospital steward to say, "Doctor, this man, or woman, is a chloral-fiend," or an "opium-fiend," or a "cocaine-fiend." Indeed, the cases were quite indifferent as to the particular intoxicant, using one or the other as chance might determine. All used some form of alcohol when obtainable, but many were habituated to the use of other intoxicants of the class mentioned. This fact primarily determined the choice of the remedy uniformly directed.

It will be observed that here was a particularly unfortunate class of cases to treat. All, even though young in years, were old sots; many had had numerous attacks of *mania à potu;* many were addicted to the use of intoxicant drugs; many were the subjects of chronic alcoholic lesions, and of other loathsome and enfeebling diseases indirectly connected with their mode of life. They were, as a class badly fed, badly clothed, and badly housed, when not in jail or in the almshouse, and certainly no luxuries were furnished them at either of these places. Almost without exception, even with those that were not at any time delirious, they were without desire for food, often nauseated, sleepless, full of pain, muscular and articular, tremulous in tongue, hands and legs, and full of nameless terror.

In no single instance that I remember was the appetite for stimulants lost. Almost invariably the victims begged piteously for drink, which in no case was given them.

The jail-fare consisted of weak coffee, with coarse brown-bread for breakfast; some kind of soup, not very rich, with plenty of brown-bread and a chunk of poor meat that had been boiled with the soup, for dinner; no supper.

The cases slept in locked cells on sacks of straw on iron bedsteads without blankets, even in the quite cool weather of spring or fall. No pneumonic or pleuritic complications ensued from this exposure.

The second series of 1054 cases, of which 47 were maniacal, presented substantially the same history, were treated in the same manner, and with the same result. Besides these, two fatal cases occurred. In one instance, the patient was brought in after my daily rounds, in a condition of alcoholic coma, and died before I saw him. He was supposed by the officers of the jail to be in that heavy drunken sleep so common with these subjects, and was left to sleep off the effect of his potations without having been given anything whatever. He was found dead in his cell in the morning, apparently without having recovered consciousness. Whether this was a purely alcoholic effect, or if he had taken also, or alone, an overdose of chloral or morphine, or whether it was uremic coma, cannot be said, as I did not see him during life, and no post-mortem examination was permitted.

The second fatal case also came in in the evening after my rounds. He was said to be quite drunk, but was able to walk to his cell, which was on the sixth tier. He became somewhat delirious in the night, but not sufficiently so to make the night-officer think it worth while to transfer him to a cell on the ground floor, where all cases with mania are kept. In the morning, when his cell was opened, he sprang over the railing and fell to the stone pavement, receiving such injuries as to cause his death within half an hour.

Neither of these deaths can therefore be fairly charged to the plan of treatment, nor are they included in the 87 cases of *mania à potu*, since, as I had not seen the one before death, or the second before the fatal injury, I am unable properly to classify them. In the second series of cases 4 were characterized by great mental excitement, noise, and violence, without terrifying delusions. They, like all of the rest, had been drinking up to the time of arrest, and were given no alcohol after arrest. Of the second series 13 (of 47) were admitted with delirium tremens, and in the remainder (34) delirium developed after admission—in one case as late as seventy-two hours after. In no case did the delirium last more than five days. The average period at which these patients were enabled to do some kind of light work was about two days after treatment was begun; they were not then in such condition as to be declared convalescent, or, if they had been in private practice, to be allowed to leave the house; but here, where they were under constant observation, and where no opportunity to obtain drink existed, they were allowed to do such work as they desired, and all drugs were then generally stopped. Usually on the second night, but often not until the third, they slept fairly well; and by this time they also began to eat with apparent relish the coarse prison-fare. Food was offered them at each meal, but no attempt was made to urge it upon them if inclination did not prompt them to eat. In a very

few instances, milk, eggs, light bread and tea were substituted for the regular prison-fare, but these were seldom taken, and were usually withdrawn when appetite returned and a good sleep had been had.

No distilled or fermented drink was given in any one of these cases—no drug but potassium bromide, except in a few instances, in which great cardiac weakness prompted the use of tincture of digitalis (ten drops) and ammonium carbonate (five grains), or occasionally in very noisy subjects, in which morphine (one-fourth grain), and atropine (one one-hundredth grain), were administered hypodermatically, at night. Thus, it is seen that in 2012 cases of chronic alcoholism with acute explosions, 87 of which were maniacal, under circumstances of the most depressing character, all did well without the use of alcoholic stimulants. My conviction is strong that it was to the withholding of the alcohol, rather than to the administration of the drug, that the good results obtained were primarily due. No restraint, further than keeping the patients in a locked cell while delirious, was exercised. The patients walked their cells incessantly, and often destroyed the bedding in pursuit of imaginary enemies; but as it was of but little value they were allowed to do so, rather than bind them in bed, or even secure the hands. As the patients were usually alone at night, in a dark cell, I found that when they were bound it added greatly to their terror, and intensified the maniacal symptoms. I am moreover convinced that the unceasing walk, with its resulting weariness, tended to the induction of sleep at an earlier period than would otherwise have been the case. In no instance, beyond a few slight bruises, did any harm result from the absence of bonds. I have not observed that alcoholics are ever disposed to injure themselves. When injury is sustained it is in flight from imaginary evils, or in struggling to obtain drink. All attempts to secure the patient in bed, to bind or muffle the hands, are unnecessary. If he is securely locked in a cell, or by himself in a room, made bare of all superfluous articles, he is unlikely to harm himself. Friends or attendants within call or sight reassure him when his hallucinations are terrifying, but he needs no restraint from them, and may be allowed to wander about his apartment without let or hindrance, with advantage to himself, provided the windows are secure.

I have treated a number of cases of delirium tremens in private practice and in hospitals during the period covered by this record, but not with such results. Fatal cases are not uncommon in hospital, and almost as frequent in private practice. This I believe is mainly attributable to the fact that neither at home nor in a general hospital is it possible to withhold stimulants or such drugs as morphine and chloral, from consideration of other inmates of the home or ward. It must be remembered, however, that cases are usually carried to hospital for some disease-complication, whilst the merely drunken and disorderly are taken to police-stations and thence to jail.

Before closing this short report it may be well to add that nearly all of the cases considered were committed to jail for thirty days; this brief period of enforced abstinence exerted no appreciable influence on the disposition to the intemperate use of strong drink, since the cases almost invariably returned in from one to three months, and often within as many days, after release.

The study of the foregoing cases leads me to the following conclusions:

1. That the clinical phenomena attending excesses in the use of alcohol are the direct result of over-stimulation, and are not due to the abrupt withdrawal of the stimulus.

2. That though ability to swallow and retain stimulants is frequently wanting, the desire for them almost uniformly persists.

3. That alcohol in any form or quantity is unnecessary in the treatment of such cases, and is usually hurtful.

4. That the absolute and immediate withdrawal of alcohol is of the first importance in the treatment of all of the symptoms due to its excessive use, even in cases characterized by great feebleness and inability to partake of food.

5. That forced feeding is rarely necessary, and is of doubtful utility in most cases.

6. That for the protection of the patient no kind of bonds is called for, and, when necessary, for the protection of others, or for the contents of the room, they injuriously affect the mental state of the patient.

CLINICAL LECTURE.

EXTENSIVE RAILROAD INJURY; AMPUTATION —FISTULA IN ANO—PERITONITIS.

A Lecture delivered at Harlem Hospital, New York, April 20, 1892.

BY THOMAS H. MANLEY, M.D.

THE first case that will demand attention is one of extensive railroad injury of the left leg, which involves a compound dislocation of and fracture into the ankle-joint, besides a horizontal fracture through the astragalus. In fact, from the description that the house-surgeon sent me, immediately after the case was admitted to the hospital, it was conclusive that the limb must be sacrificed.

The history of the case is not without some interest and practical value; hence I will give it rather fully, as well as make a few observations on amputations necessitated by railway injuries. It is now thirty-six hours

since the injury was sustained. The patient is apparently a healthy man, twenty-three years old, with no organic disease. He says that while mounting a train in motion he was pushed off by the guard, and that the limb was crushed when he fell. The ambulance-surgeon arrived at the railway station about half an hour after the accident. He reports that he found the man bleeding very freely and in profound shock. Temporary dressings were applied; the hemorrhage was controlled, and stimulants were given. When the patient entered the hospital, though quite blanched, with a feeble pulse, he was somewhat hilarious. Great importance attaches to this feature of intoxication of the injured in railway or other accidents. But we must always be guarded in giving an opinion on this point, for we know that, particularly in cities, immediately after an injury, with the first signs of syncope, some sympathetic bystander is pretty sure to dose the patient with alcoholics, and we can see that, as in a case of this kind, when there has been great loss of blood, a small quantity of stimulant may cause great excitement.

It might be asked why we did not do a primary amputation as soon as the man entered the hospital, in order to avoid the dangers of hemorrhage, tetanus, etc. We did not for two or three good reasons. The first was because the patient would not then consent to the operation, and the next was that he was in such a state of collapse at that time that, even though there were no objection, we would decline radical measures. Exclusive of these reasons, primary amputations are now almost never resorted to in this hospital. By delay in railroad injuries of a limb, in children particularly and in the young, we can always better appreciate just how much must be sacrificed. Indeed, in not a few cases that have at first presented but a gloomy aspect the circulation has in time become reëstablished; what has at first seemed a hopelessly destroyed limb has been saved.

In railroad disorganization of a limb it is important to note that the same agency that effects the local disorganization, by its sudden, violent concussive force, also conveys a great shock to the nerve-centers or the fixed glands, so that even though our patient should safely survive amputation, other complications may arise that may invalid the patient, and though the amputation do well our patient may suddenly succumb after reaction has set in.

As to the technique of amputation, I would say that there are two points, mainly, that should always be observed, viz., to spare as much bone as possible, and so to form your flaps that they maintain their vitality until healing is complete. The usual rules set down in the text-books have but little application in amputation for traumatisms.

Our next patient comes to us with a fistula in ano. He is a man, thirty-seven years old, who always enjoyed good health until six months ago, when he commenced to suffer from piles. These were later followed by a perineal abscess, which was opened and evacuated one month ago. Since then he has had a fistula. He says that no wind or feces escape through it, and on examination with a probe and by injection no internal opening can be found in the bowel; hence we must assume that he has what is known as an incomplete external fistula. This is a good case to demonstrate how easily and safely these cases can be operated on by the employment of cocaine. It greatly simplifies the operation, so that practically no assistants are needed, the patient himself holding the buttocks apart, while the cocaine solution—no stronger than one per cent.—is injected in a radiating direction into and through the sphincter. Now the sphincter is widely dilated, the parts cleansed, and the mucous membrane mopped with the same solution, and we are ready to cut; this, you see, is accomplished without pain or inconvenience. The parts are now flushed and cleansed, the man gets up and walks into the ward, rests an hour, and goes home.

Here are two cases of peritonitis—one coming on two weeks ago, the man having been run over. There was evidence of hemorrhage into the cavity of the peritoneum. Rest, inunction of mercury, opium internally, with hot topical applications, have set him right again, and he goes out to-morrow. The other case is evidently of appendicular variety, and was sent in to me for laparotomy and appendisectomy. We did not regard an operation as necessary. Our line of treatment was essentially the same as in the other case. The man, as you see, is as spry as a kitten. He goes home to-day, after having been in the hospital just eight days.

CLINICAL MEMORANDA.

OVARIAN CYST IN A GIRL TWELVE YEARS OF AGE.

BY CHARLES F. DAVIDSON, M.D.,
OF QUEENSTOWN, MD.

ON January 5, 1892, I was called to M. H., who, her mother told me, "had a lump in her stomach." The girl was born May 19, 1880, and was, therefore, nearly twelve years old. She had never menstruated; was fairly well-developed; in good health; and had always been in good health. The mother had noticed the "lump" two weeks previously, and, as the patient had suffered with nausea, sometimes with vomiting, the mother had become alarmed, and consulted me. On examination I found an enlargement in the lower part of the abdomen, in the middle line, just above the pubic arch. To the hand it conveyed the sensation and was about the size of a gravid uterus at about four and a half months. The vagina was large for a child of her age; the cervix uteri was long. I suspected pregnancy, and gave a tonic as a placebo, and directed the patient to take plenty of out-door exercise. I saw her several times in the course of the following week, without being able to determine the exact nature of things. On January 21st I gave her chloroform, and made a thorough examination. I found that the lump was rapidly increasing in size, and that the patient had begun to lose flesh. I now excluded pregnancy, and diagnosticated ovarian tumor. On account of the rareness of ovarian growths in the young, on January 22d I took Dr. Corkran, of Centreville, Md., to examine the case with me. After a careful examination, under chloroform, he concurred in my diagnosis, and we advised an operation at once. After thinking the matter over for twenty-four hours, her parents—illiterate persons—refused to allow of operative interference, saying that they would rather the child should die. The tumor steadily increased,

and, by February 27th, entirely filled up the lower part of the abdomen. Cough became most distressing, and the lower limbs much swollen. On March 19th the girl died, being just eleven years and ten months old.

I requested and obtained permission to make a post-mortem examination. On opening the abdomen I found a multilocular ovarian cyst, firmly adherent to the peritoneum. Introducing a trocar I drew off about a gallon of fluid of the consistence of syrup. On account of the firm adhesions, the tumor was with great difficulty removed. It had a pedicle, about two inches long, originating from the right ovary, the left ovary and uterus being perfectly normal. The small intestine for a distance of eight inches was bound to the upper surface of the cyst by firm adhesions. I punctured several more cysts, and collected another gallon of fluid of the same sort as that found in the cyst first punctured; then the solid part of the tumor weighed twenty and a quarter pounds. All of the other organs were normal, except the spleen, which was very soft.

The case reported is particularly interesting for two reasons: First, the age of the patient, and, second, the very rapid growth of the tumor.

Scanzoni records 97 cases, of which 70 were from eighteen to forty years old; Chéreau, 230 cases, of which 133 were from seventeen to thirty-seven years old; Lee, 135 cases, of which 82 were from twenty to forty years old. Of Scanzoni's, 5 were between fifty-five and sixty.

In the *Medical Press and Circular* for March 26, 1873, a case is reported in which ovariotomy was successfully performed on a child six years old.

Mr. Safford Lee collected statistics as to the duration of the disease in 123 cases not subject to curative surgical treatment: In 38 the duration was one year; in 25, two years; in 17, three years; in 10, four years; in 4, five years; in 5, six years; in 4, seven years; in 3, eight years; in 17, from nine to fifty years.

Judging from the increase in the size of the tumor after I saw it, it could not have been growing more than six weeks previously; the patient died in less than eleven weeks after I first saw her. I have not found a case in the literature of the subject that pursued so rapid a course. As for the age of my patient, there have been cases as young or younger, but they are exceedingly rare.

A FATAL CASE OF THROMBOSIS OF THE LEFT MIDDLE CEREBRAL ARTERY.

BY EDWARD A. BALLOCH, M.D.,
OF WASHINGTON, D. C.

AT half-past one on the morning of April 18th I was hurriedly called to Mrs. C., a widow, white, sixty-five years of age. When I reached the house I found her *in articulo mortis*, and she died within three minutes after my arrival.

Upon inquiry, I learned that she had always been a healthy, vigorous woman, but that for the last five or six years she had frequently experienced a sense of numbness in the right hand and arm, and some confusion of sight in one eye (which one I could not definitely ascertain).

On the day preceding her death she had seemed more than ordinarily cheerful and strong, and had gone to church three times. Sometime after midnight, her granddaughter, a child of twelve, who slept in the same room with her, was awakened by an inarticulate sound emanating from the throat of her grandmother. The child screamed and aroused the family. When they reached the room Mrs. C. was found to have vomited freely and to be unconscious. The stupor continued until death.

I also learned that the mother of the deceased had died from "paralysis," after an illness of three days. One son presents an arrest of development in the left arm, due to paralysis occurring when he was six months of age.

An autopsy was performed April 18th, 11 A.M., ten hours after death, by Dr. D. S. Lamb. Fluid was found in both pleural cavities, and there was moderate edema of the lungs. The heart was normal as to size, thickness of walls, and condition of valves. The abdominal viscera were normal, the stomach being perfectly empty. The dura mater was adherent to the skull-cap. The pia and arachnoid were injected. The choroid plexus was the seat of large cysts. The arteries at the base of the brain were extensively atheromatous. In the left Sylvian artery was found a firm, red clot, completely plugging the vessel for one-third of an inch beyond its origin. The pons and medulla were normal.

Remarks.—Death from thrombosis of the Sylvian branch of the middle cerebral artery is not common. The anastomoses between it and the other cerebral vessels are usually so free as to allow of the ready establishment of the collateral circulation. In this case the probable explanation of the fatal termination is as follows: After a day of more than usual excitement and action, there was at night a corresponding reaction and relaxation of the vital forces. The circulation became sluggish and stagnation occurred in the atheromatous and narrowed vessel, and the heart had not force enough to drive sufficient blood through the remaining vessels, which were diseased and lessened in caliber, and death accordingly resulted from acute anemia of the brain. The pulmonary edema was coincident and passive only.

EXPULSION OF A GALL-STONE OF GREAT SIZE.

BY P. C. WILLIAMS, M.D.,
OF BALTIMORE, MD.

EARLY in March of this year (1892) I was called to see an old lady, seventy-two years old, who was suffering from an attack of cholera morbus, caused by imprudence in diet. The pain and diarrhea were soon relieved, but the vomiting persisted. After a few days the old lady vomited fecal matter in great abundance. This, of course, led me to suspect intestinal obstruction, and after careful investigation I discovered in the ileo-cecal region a well-defined oval tumor, about two inches in diameter. I inferred that this tumor was an intussusception of the bowel produced by the prolonged vomiting.

On several occasions I had relieved cases of intussusception by giving large doses of chloral, and keeping the patient profoundly under its influence for from thirty-six to forty-eight hours, during which time the constriction of the bowel became relaxed, and the intussusception

was relieved. Recalling these cases, I gave large doses of chloral and morphine, which were promptly vomited. I then administered an enema of thirty grains of chloral, and two drams of fluid extract of senna every two hours.

This treatment produced profound sleep, and at the end of thirty-six hours my patient was relieved by the passage of an immense gall-stone per rectum. The stone was a *smooth cylinder, one inch and five-eighths long*, with a diameter of *one inch and one-eighth*, and a circumference of *three inches and five-eighths*. Both extremities of the cylinder were smooth and spherical.

After the passage of this stone the old lady rapidly recovered her health, and is now better than she has been for several years. This case and its fortunate termination were of great interest to me.

Upon inquiry I ascertained that last July (1891) this lady had a very severe illness at Atlantic City, which was thought to be due to peritonitis. From this attack she slowly recovered, but continued in delicate health until she came under my care for the first time last December (1891) with an attack of "grippe." She soon rallied from the "grippe," and in March (1892) again came under my care as described.

I have no doubt that during her illness at Atlantic City the gall-stone found its way by ulceration of the gall-bladder into the intestine, and gradually passed down without special symptoms until it reached the ileo-cecal valve, where it was arrested and caused the fecal vomiting that disclosed the true nature of her sickness.

The points of special interest in this case were: First, the great size of the stone—the largest I ever saw; second, its prompt and safe expulsion through the valve under the prolonged use of large doses of chloral and senna.

THERAPEUTIC NOTES.

Paralytic Obstruction of the Intestine Relieved by the Constant Current.—SEMMOLA (*Internationale klin. Rundschau*, 1892, No. 16, p. 641) has reported the case of a man, twenty years old, of nervous temperament, in whom, after the occurrence of diarrhea, symptoms of intestinal obstruction appeared; to these ischuria was added. Ordinary treatment was without avail, and celiotomy was proposed. From the suddenness of onset of the symptoms of obstruction after the occurrence of diarrhea; from the paroxysmal character of the pain; from the coëxistence of paralysis of the bladder, without previous disease; and from the neuropathic tendency of the patient, a diagnosis of paralysis of the bowel was made, and the application of the constant current was recommended. The positive pole, attached to a catheter, was introduced into the rectum, and the negative pole stroked upon the abdomen in the course of the colon. The applications were made for from eight to ten minutes thrice daily. The symptoms gradually improved, and, after the ninth application, the bowels were spontaneously moved. In the course of ten days the patient was completely restored to health.

The Treatment of Pneumonia.—From an extensive study of the mortality of pneumonia under different modes of treatment, REED (*Therapeutic Gazette*, Nos. 3 and 4, 1892) concludes that water, locally applied, either as the wet-pack or as the bath after the method of Brand, is the most efficient single therapeutic measure for acute pneumonia. In the first stage of the disease, veratrum viride or aconite can accomplish more than any other drug; and in the second stage the same is true of digitalis. A combination of one of these cardiac sedatives with opium and diaphoretics constitutes a safe and successful internal treatment in the first stage, being capable of aborting the disease if the administration is begun near the onset and is repeated at short intervals, day and night. Venesection, though a most efficient procedure in the treatment of pneumonia of sthenic type and, judiciously employed, considerably more successful than expectant measures, is no longer an indispensable resource in managing the disease, as other remedies have been found to accomplish the same results more surely and more pleasantly.

Radical Treatment of Dacryocystitis.—GUAITA (*Centralbl. für prakt. Augenheilk.*, No. 1) recommends curetting the lachrymal canal and the introduction of a decalcified bone tube into the duct previously divided, for the relief of dacryocystitis. The tubes are prepared from the bones of the hind-legs of large turtles; the bones are treated with dilute hydrochloric acid, and the medullary cavity cleansed; the tubes are kept in absolute alcohol and a solution of mercuric chloride, 1 : 500. They should average about an inch in length, and from a tenth to an eighth of an inch in diameter. After the lachrymal canal is opened and curetted, it is cleansed with gauze saturated with a solution of mercuric chloride, 1 : 2000; the tube is introduced, and the wound is closed with one or two sutures. A compress wet with a cold solution of mercuric chloride is afterward applied. Unless severe inflammatory symptoms be present, a cure can be expected in from four to six days.—*Wiener medizin. Presse*, 1892, No. 15, p. 594.

The Treatment of Pleurisy —In a communication to the French Academy of Medicine, WEST (*Bull. de l'Acad. de Méd.*, xxvii, 3, 14, p. 484) states that pleurisy purulent from the outset is much more common in children less than twelve years old than in adults. If in a case of frank pleurisy with effusion absorption has not begun in the course of eight days, puncture ought to be made. In a large number of cases of purulent pleurisy in children, a single puncture suffices, if care be taken to prevent the entrance of air and if the wound be hermetically closed. It is scarcely possible to puncture too early.

Atropine as a Hemostatic.—DMITRIEFF (*Wratsch*, 1891, No. 50) reports the successful employment of atropine as a hemostatic in two cases of metrorrhagia. In one case the hemorrhage persisted, despite the employment of the usual remedies, including the tampon; but ceased after four injections each of gr. $\frac{1}{24}$ of atropine. The second case occurred in an anemic woman, who became syncopal, with cold extremities. The first injection was followed by improvement, and the third by cessation of the bleeding. In both cases the pupils were slightly dilated.—*Wiener medizin. Presse*, 1892, No. 16, p. 639.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 2, 1892.

THE PULMONARY COMPLICATIONS OF INFLUENZA.

AMONG the recent valuable contributions to the subject of influenza is a lecture upon the pulmonary complications of the disease, delivered at the Pennsylvania Hospital, by PROFESSOR DA COSTA.[1] The paper is the more valuable because the author's experience with the disease is not confined to recent years. He calls especial attention to the great variation in type of the respiratory disorders encountered in different epidemics, and to the not inconsiderable variation even among the cases met with during any one epidemic.

While in some previous epidemics there was observed merely a catarrh affecting the upper air-passages, with laryngeal and bronchial involvement, but with little tendency to spread to the deeper parts of the lungs, the recent visitations have been characterized by the tendency of the morbid process to affect the pulmonary parenchyma. The chief pulmonary complication of influenza in the recent epidemics, as illustrated by a typical case exhibited by PROFESSOR DA COSTA, was an intense congestion, often, though wrongly, called pneumonia. With rapid breathing, harassing cough, and evident oppression, there was found slight impairment of percussion-resonance at the lower part of the chest, especially posteriorly, and frequently the more marked on one side, but without decided dulness or evidence of consolidation. The breath-sounds at the lower part of the chest were feeble and ill-defined. There were numerous fine râles. The expectoration was rather tenacious, but not decidedly viscid, and not rusty.

The attack often began, as does true pneumonia, with chill or chilly sensations, which might occur early in the course of the influenza, or some days after the ordinary symptoms of the latter had been manifested. The fever subsided gradually and regularly, or gradually and irregularly, and but rarely by crisis. Crises, however, did occur exceptionally, and DR. DA COSTA reports a striking instance.

The cardiac complications added to the embarrassment of the circulation. The heart was quick, feeble, and irregular. Short systolic apex-murmurs were not uncommon, but much more general were a defective first sound and a sharp second sound. Sudden movement involved the danger of fatal syncope. A case is reported in which death resulted during an attempt of the patient to raise himself to use a bedpan. The autopsy showed a white clot, evidently ante-mortem, in the right side of the heart, extending from the auricle into the ventricle. The left chambers were empty and contracted. To the eye the muscular structure appeared normal.

The most prominent nervous phenomena were insomnia and delirium. To the latter, DA COSTA gives the name of "business delirium," because the patient's mind persistently dwells upon his ordinary occupations. This type of delirium was noticed more particularly in professional and business men. In many cases, especially in the graver, albuminuria, associated with the presence of tube-casts and other signs of actual renal involvement, was observed. The albuminuria was not persistent, but passed away with the attack. It was found in cases without delirium, and delirium was observed without the occurrence of albuminuria.

DA COSTA believes "that we are wrong in combining the statistics of 'influenza lungs' with those of pneumonia; that we are wrong in basing our treatment upon the view of their identity; and that we are doubly wrong in deciding against the value of remedies which we have learned to depend upon in ordinary pneumonia, because they may fail us in the lung disorders of influenza."

[1] International Clinica, vol. ii, second series, reprint.

It is true that there are cases in which, after death, are found appearances indicative of true croupous pneumonia, but these are comparatively rare, and the author, while he does not express a positive opinion, seems inclined to look upon the pneumonia as an epiphenomenon rather than as an essential element of the disease. Among the cases that he reports is one of croupous pneumonia following influenza, in which death resulted from pulmonary edema.

The treatment upon which PROFESSOR DA COSTA particularly relied consisted chiefly in the administration of large doses of ammonium salts, with quinine, with most carefully sustained nutrition, and in many cases with digitalis and with stimulants. Absolute rest was insisted upon; the patients were even made to take their medicine from a tube, to avoid the danger of sudden heart-failure from the exertion of rising. Digitalis is a remedy often used in a routine manner, and thus much abused; nevertheless, properly watched and used intelligently, the author attributes much value to it. Strophanthus was sometimes used in cases in which digitalis did not seem to be well borne, and strychnine was given in alternation with digitalis, or alone. In all cases in elderly persons, with atheromatous vessels, strychnine is a safer remedy than digitalis, for the latter so increases arterial tension that in one instance the brittle vessels gave way and an extensive cerebral hemorrhage resulted. Potassium iodide was disappointing, so far as any effect upon the pulmonary conditions was concerned, but DR. DA COSTA believes that ammonium iodide is worthy of large trial. Except in instances of great prostration, extensive dry-cupping was extremely useful. Poulticing or wrapping the chest in huge layers of wool and cotton renders the patient uncomfortable and hot to an extraordinary degree, interferes with examination of the chest, and exerts no beneficial influence. Only in instances complicated by pleurisy, or in lingering consolidations, would the author recommend the use of poultices.

Bleeding may produce some amelioration of symptoms in certain cases, but exerts no remedial influence. Oxygen likewise seemed to DR. DA COSTA to be devoid of curative effect, though possessed of palliative virtue. Many cases recovered without the use of alcohol; on the other hand, alcohol was often used freely, and seemed especially useful in cases complicated by true lobar pneumonia.

Nitro-glycerin was beneficial in cases in which the element of congestion was marked. Strophanthus was used coincidentally to steady the heart. Of hypnotics, paraldehyde, sulphonal, and hyoscine were the most dependable, hyoscine being the best of these.

In cases with rapidly extending bronchitis and edema, no certain treatment could be depended upon, yet a case is related in which recovery took place notwithstanding the desperate nature of the symptoms. So far as treatment may have influenced this case, recovery seemed to be due to persistent dry cupping and the free administration of ammonium salts, quinine, strychnine, and stimulants.

Not the least element of value in the observations of DR. DA COSTA, here abstracted, is their judicial tone. Representing the matured conclusions of an unusually well-qualified observer upon matters concerning which considerable differences of opinion have been expressed, they are of permanent importance, and THE NEWS has, therefore, so far departed from its custom as to present them in this column.

IMPOTENCE.

THE NEWS has received a letter from an individual who signs himself "A Sufferer," who inquires "for a friend," if impotence is curable, and if the confident claims of the quack circular are to be looked upon as eternal truths.

This communication brings to mind a large class of patients difficult of treatment, and we cannot help feeling that many of them wander off to quacks because of lack of improvement at the hands of the general practitioner, who is too likely to rely on the oracular utterances of the clinical index, and settle on the routine of sexual stimulation as the proper course to pursue.

The causes of impotence are almost as many as the causes of ill-temper, and the treatment must be suited to each particular case. In view of the fact that in a recent work on circumcision the author confuses impotence and sterility, it may not be unprofitable to discuss the modern views upon these subjects.

By impotence is meant an inability to successfully perform the sexual act. This may result from some congenital malformation, or distortion of the sexual organs, as great hypospadias, absence of the testicles, or excessive brevity of the penis; or some pronounced organic disease, as testicular atrophy, varix

of the dorsal vein of the penis, calcification of the fibrous septa of the penis, etc. All cases belonging in the foregoing class are designated as examples of organic impotence. Many of them are incurable, but some may be relieved by operation.

Impotence may result from a mental condition when the organic apparatus of erection is entirely normal. It may arise from mental preoccupation, exhaustion, worry, personal aversion, bad temper, excessive anxiety to play a creditable part (as on a wedding night), or a fear of failure, and a host of other conditions as various as the emotions of man.

This condition may be occasional or persistent. It is purely a morbid mental state, and treatment to be successful must be directed to the mind. The accidental or occasional cases of psychic impotence need to be reassured, and often given a placebo. The persistent cases require very careful guidance. JOHN HUNTER had a patient, recently married, who was unable to have an erection. HUNTER gave some indifferent drug, directed the man still to sleep with his wife, but under no circumstances to have intercourse. These instructions were violated almost as soon as given. Again, impotence may be symptomatic of some other diseased state, as opium or chloral eating; bromism, and chronic poisoning by lead, arsenic, and mercury; injuries and diseases of the cerebro-spinal nervous system, as concussion, spinal meningitis, locomotor ataxia, and advanced paresis, and of such conditions as albuminuria and diabetes. In not a few cases of symptomatic, as in other forms of impotence, the loss of power is preceded, and in some cases accompanied by inordinate desire. Its onset is likely to be marked by imperfect erections and premature discharges, and its treatment is that of the causative disease.

An enormous majority of the impotent is composed of those who labor under loss of tone. To the late PROFESSOR S. W. GROSS belongs the credit of conclusively proving that "impotence is generally produced by subacute or chronic inflammation and morbid sensibility of the prostatic urethra, which are frequently associated with stricture, and which are usually due to masturbation, gonorrhea, sexual excess, and constant excitement of the genital organs without gratification of the passions." This irritation of the prostatic urethra overstimulates and exhausts the genito-spinal center in the lumbar cord, the erections become feeble, and the ejaculations premature or belated, and, finally, erection may be impossible, desire may be exaggerated, absent, or perverted; nocturnal seminal emissions or diurnal losses are likely to ensue, and spermatorrhea may develop. There is a whole train of uncertain bodily symptoms. Hypochondria appears, and occasionally insanity.

Proper treatment, if inaugurated before insanity occurs, is almost always successful. Stricture and hyperesthesia are relieved by steel bougies (up to No. 35 French), the meatus often demanding division to admit the larger sizes. In many instances bougies alone remove the chronic inflammation, while in some they relieve, but do not cure. In this last class cold-water currents may be thrown through the return catheter; inunctions of ichthyol and lanolin, or of mercurial ointment, are made to the perineum; blisters are used on the perineum, injections of silver nitrate, or other astringents, are thrown in by the deep-injection apparatus. Seminal losses are controlled by bromides and atropine, with hot hip-baths, hyoscine hydrobromate, or camphor monobromate. After the seminal losses cease, and the hyperesthesia is abolished, it may be necessary to give a tonic course of treatment. Strychnine and dilute phosphoric acid, or strychnine, arsenic, iron, and quinine, may be employed.

We have in the foregoing remarks only hinted at the treatment of these troublesome cases, but we hope that we have shown enough to remind the general practitioner that to cure impotence requires some knowledge and some skill, and a larger armamentarium than a syringe with zinc sulphate and a bottle containing the acid phosphates, or cantharides, or potassium bromide.

SELF-REFUTED.

THE following extract from an editorial article in the *Practitioner's Monthly* for May, 1892, opposing the ground taken by THE NEWS and the American Medical Association against the use of secret nostrums, furnishes so complete a refutation of the other portions of our contemporary's argument, that, despite its numerous misstatements of fact, we cannot refrain from printing it verbatim:

"The arbitrary test proposed by our cotemporary, 'that the full process (of manufacture) is of public record, or the true and exact composition of the finished product is made known,' is palpably absurd, since to do this would give away the secret. Antipyrin is said to be subject to chemical analysis or test. So are phenacetin and sulphonal subject to chemical analysis or test, but how much wiser is anyone as to the process of manu-

facture? Someone gave away the secret of manufacture of acetanilide, and the consequence is that antifebrin has ceased to have a market value. Does any sane man suppose that if the process of manufacture of antipyrin or any of the other of these so-called proprietary preparations were actually known, that they would not be put on the market under another name, the same as acetanilide has? What better illustration is needed than the one just cited of acetanilide, which sells for fifteen cents an ounce, and antifebrin for one dollar?"

What an excellent weapon our opponent has unwittingly placed in our hands!

PRESCRIPTION-WRITING EXTRAORDINARY.

À PROPOS of the interest taken of late by the manufacturers of pharmaceutical preparations in the education of physicians, we beg to call attention to a recent issue by a Philadelphia firm of a *Therapeutic Reference-Book*, which, it must be admitted, contains some valuable information for physicians; but in a section on prescription-writing the author has evidently essayed a department which he should have left untouched, since even the highly valuable aid of abbreviation fails to cover his utter ignorance of the rules of Latin grammar upon which prescription-writing is based. Thus we have the following:

℞.—Potass. Cynanide.
Potass. Brom.
Ext. fl. Pru. Virg.
Syr. Simple et.
Aqua. Dist. q. s.

Again—

℞.—Hydr. Chlor. Mit.
Soda Bicarb.
Pulv. Cinnamom.
Sach. Lact.
Mix et. divide *into* charta*e* No. xii.
S.—One every two hours.

Had the writer been satisfied to put the whole into good English we should not have complained, but the pitiable conglomeration of English and Latin which is placed before the physician with a view to his *instruction* should be exposed. We are not averse to learning from anyone, but we do protest against the confiding physician who happens to be ignorant of Latin being taught stuff, the adoption of which must excite a smile in the well educated apothecary who compounds his prescriptions.

To Relieve Headache.—WEISS (*Prager med. Wochenschr.*, No. 15, 1892, p. 159) has observed that temporary relief from headache could invariably be afforded by pressure upon the abdomen at a point midway between the umbilicus and the ensiform cartilage, the mechanism of which is thought to be dependent upon compression of the aorta.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-third Annual Session, held at Detroit, June 7, 8, 9, and 10, 1892.

SECTION ON DISEASES OF CHILDREN.

FIRST DAY—JUNE 7TH.

The Chairman, DR. E. F. BRUSH, of Mt. Vernon, N. Y., in opening the session, read a paper on "Scorbutus in Children." He stated that man is the only animal that not only kills his food before eating it, but makes it *absolutely* dead and, if possible, sterilizes it. The chemist of the day would make us believe that man needs for nourishment only so much nitrogenized and so much non-nitrogenized matter; that a little jar of beef-extract is far superior to ten pounds of meat as found in nature; that milk that has been skimmed, dried, powdered, and thoroughly sterilized is preferable in every way to fresh milk from Nature's laboratory. The statement has recently been made that when the chemist had reached his goal, armies would be able to carry in a small vial supplies for several days, instead of the load of meat and bread they are now obliged to carry. The peasant in the famine-stricken countries, the sailor and soldier when deprived of fresh living food, are all subject to scurvy. Dr. Brush expressed the opinion that the constant use of dead food for infants is wrong; patent baby-foods should be absolutely excluded, and the young thus be guarded from many evils. No greater field exists for the pediatrist than the study of infant feeding.

DR. F. S. PARSONS, of Boston, read a paper entitled "Ought Infants to be Washed Immediately after Birth?" He stated that all wild animals wash their young directly after birth. The human mother, however, cannot perform such duties in the manner of the lower animals, whose offspring, moreover, are covered with hair, necessitating simply the drying of a wet surface; but the child with practically no hair on the body is ushered from an aqueous solution at a temperature of about 100° F., to an aërial temperature of from 20° to 30° lower. Apparently to guard against this sudden cold, Nature has placed a sebaceous covering, which, if allowed to remain, would protect the child from the chilling influences of the reduced temperature. Dr. Parsons, however, does not so much object to the washing of the child as to the manner in which it is generally done, and which so often leads to catarrhal troubles, varying from simple snuffles to broncho-pneumonia. He recommends a little skirt with sleeves and hood, made of some soft unirritating material—for example, Canton flannel—in which the infant should be placed, after being quickly rubbed with pure hog's lard. Here it should remain for four or five days, when it would become accustomed to the lowered temperature, and could with much more safety be washed; but as this would not satisfy the average mother, he would advise covering the head and body with lard, then quickly placing the child in a tub of water at about 103° F., there cleaning and washing the body with a soft linen cloth. He has never seen a child so treated suffer from catarrhal troubles in any way.

In the discussion that followed the reading of the paper, DR. ULRICH, of Pennsylvania, stated that he had long been convinced that there was too much washing of young infants; the nurse seems often only to know that the child must be immediately washed and dressed; he thought that the children lived in spite of the nurses. Soap and water would not touch a heavily-coated child; only oil would do this. He would not dress the child until the day after labor. The inevitable flannel bandage, he thought, was generally rolled too tightly, and put on regardless of the weather, in hottest August as in cold December.

DR. PRESBERY, of Taunton, Mass., felt that he would be greatly criticised if he left a child go twenty-four hours without washing; he agreed that infants are too much washed; the sebaceous coat is applied for the protection of the child *in utero*, and is not intended to remain after birth. He would have the child immediately washed and put in dry absorbent material.

DR. BROWN, of Illinois, thought the people of his State would insist on the band as necessary to hold the umbilicus in place, but he used a linen band in summer.

DR. WIRT, of Indiana, put the band on very loosely, and put on as little clothing as would keep the child warm; he would wash the child twice a week, or at most every other day.

DR. BRUSH, of New York, expressed the thought that the child often suffers more than the mother, and that the crying is a provision of Nature to open the lungs, into which, sometimes, some of the amniotic fluid is drawn, causing a bronchitis, which might be charged to the first bath.

DR. PARSONS closed the discussion by adding that he did not so much object to the early washing as to the manner in which it was done. He would have the child washed, say, only once a week, after the initial bath. He did not employ a band of any kind, believing that they often caused hernia; instead he used dry cotton, held in place by adhesive plaster, which could be easily removed, and after that he employed nothing.

DR. W. S. CHRISTOPHER, of Chicago, read a paper on "Starvation-neuroses." He called attention to the important etiologic relation that malnutrition of the tissues generally bears to the development of various functional nervous diseases and the neurotic symptoms that accompany many other pathologic states.

Chorea, convulsions, laryngismus stridulus, various nervous affections of the bladder, and many minor pathologic nervous phenomena are very frequently starvation-neuroses, and are amenable to treatment corrective of defective nutrition. Inherited tendencies and auto-intoxication are frequent etiologic factors in these conditions, but starvation is a still more frequent one.

DR. BROWN, of Indiana, stated that he does not think that the condition is so often one of general malnutrition of the body as one of special nerve malnutrition.

DR. WATSON, of New Jersey, thought that less attention should be paid to medicines and more attention to diet and pure air.

DR. MARTINETTE, of Baltimore, stated that he had never seen the diarrhea of rickets in winter—a fact indicating that so-called rhachitic diarrhea is often due to other causes.

The discussion was closed by DR. CHRISTOPHER, who had stated that he had often seen the diarrhea in winter.

SECOND DAY—JUNE 8TH.

Morning Session.

DR. F. E. WAXHAM, of Chicago, read a "Report of Four Hundred Cases of Intubation." He stated that he felt called upon to report his cases in consequence of the many unfavorable comparisons of intubation with tracheotomy. The results that he has obtained might well make anyone an enthusiastic supporter of the operation. The following is a record of his cases:

	Cases.	Recoveries.	Per cent.
Under one year	12	4	33.33
One year	52	12	23.07
Two years	70	18	25.71
Three "	69	27	39.10
Four "	79	30	37.97
Five "	39	18	46.15
Six "	25	7	28
Seven "	25	10	40
Eight "	10	6	60
Nine "	6	3	50
Ten "	5	2	40
Eleven "	1	1	100
Twelve "	2	0	0
Thirteen years	1	0	0
Fourteen "	1	0	0
Twenty "	1	0	0
Forty-three "	1	1	100
Sixty "	1	0	0
In all	400	139	34.75

The cases all occurred in private practice. In the first 100 cases there were 27 recoveries; in the second, 34 recoveries; in the third, 40 recoveries; and in the fourth, 38 recoveries; the improvement of instruments, improved methods of feeding and management, and the almost universal administration of mercuric chloride after the first 100 cases, undoubtedly accounting for the larger percentage of recoveries. Failure may be ascribed, firstly, to the difficulty of the operation; secondly, to lack of judgment as to size of tube; thirdly, to the fact that patients are allowed to die from obstructions below the tube; and, fourthly, to lack of careful nursing and feeding. In each large city a few specialists should perform this delicate and difficult operation so as to become expert therein; in country practice tracheotomy is advised in its stead. A tube too large to be expelled only invites disaster; the attendant should be instructed to invert the patient in an emergency, when, if the tube is not expelled, the finger should be forcibly pressed against the trachea from below. A hoarse, squeaking cough, or a flapping sound, means membrane below the tube, which should be instantly removed to allow the cast to be coughed up; the patient should be fed in the inclined position; insufficient nourishment is often given. Dr. Waxham has confidence in the steam atomizer, iron, mercuric chloride, and hydrogen dioxide.

DR. HUBBARD, of Ohio, thought that a child having a much greater expiratory than inspiratory power could always expel a tube, but thought that children are sometimes strangled by sucking into the tube disintegrated membrane, or the foam from the use of too concentrated hydrogen dioxide; this latter he had seen.

DR. S. P. DUFFIELD, Health Officer of Detroit, opened

the general discussion on diphtheria by an interesting consideration of the prophylaxis of the disease. He felt that the present mode of quarantine by placarding a house almost useless, as, when the physician was gone, the inmates mingled promiscuously among their neighbors on the street cars, at the grocery, etc. Cities should have cottage-hospitals outside of city limits; say twenty acres should be divided into five acres each for smallpox, diphtheria, typhus, and scarlatina, separated from one another—where the convalescents might enjoy themselves. He would advise small, cheap, two-roomed cottages, where mother and child could be isolated, the city providing provisions and treatment, etc. This he thought the cheapest, as well as the most effective quarantine.

DR. HANNAN, of Hoosac Falls, N. Y., stated that in his city of 8000 inhabitants the little ones of the rich and poor were dying on all sides, the treatment this year seeming to have no effect whatever. Last year the disease was almost harmless, none dying; this year nearly all die. In one house, containing seven children, two took diphtheria: one lived, and one died; the other five, though they mingled every day in their very small house with the sick ones, did not take the disease.

DR. JENNINGS, of Detroit, spoke of the therapeutics of the disease. It is essential first to know what diphthera is. He felt certain that at the outset it was a purely local trouble, followed by marked constitutional symptoms. Local treatment is of the utmost importance, and, if employed early and vigorously pushed, little constitutional treatment would be needed. No remedy is a specific. It does not so much depend on which local antiseptic is used as on the manner in which it is applied. Dr. Jennings believes that spraying is overrated. He would thoroughly flush the nasal cavity and the pharynx, and treat them as any surgically infectious wound that could not be disinfected with a spray. He preferred hydrogen dioxide and mercuric chloride.

DR. BROWN, of Indiana, felt that there was something in one constitution that served as a soil for diphtheria which another lacked.

The discussion was further participated in by DRS. MOSHER, of Kansas City, Mo.; DUNMIRE, of Philadelphia; WHITE, of Indiana; SHAW, of Cincinnati; LONG, of Buffalo; MCDONALD, of Indiana; and DEVENDORF and DOUGLAS, of Detroit.

Afternoon Session.

The Nominating Committee recommended the following as the officers for the ensuing year: *Chairman*, C. G. Jennings, of Detroit, Mich.; *Secretary*, F. S. Parsons, of Northampton, Mass.; *Executive Committee:* W. P. Watson, of New Jersey; W. S. Christopher, of Chicago; and E. F. Brush, of New York, the retiring chairman.

DR. G. N. HIGHLEY, of Pennsylvania, read a paper on "Acute Meningitis, with Special Reference to Its Treatment," in which he strongly urged the abstraction of blood, either by leeches, cupping, or venesection, believing this superior to any drug. The bleeding should be done early, and often enough to relieve the engorgement, even though the ulnar pulse be very weak. He also strongly advised the constant use of cold to the head, and, if necessary, he at times gave morphine and potassium bromide. He reported three cases successfully treated in this way.

DR. W. E. WIRT, of Cleveland, read a paper entitled "Rickets, and the Treatment of Resulting Deformities."

DR. D. R. SHIMWELL, of Philadelphia, read a paper on "The Surgical Aspect of Rickets."

These papers and their discussion brought out the following points: That the most common cause of rickets is malnutrition (not necessarily under-nutrition) and bad hygiene. The claim that rickets is the manifestation of infantile syphilis was not sustained. The treatment advocated was healthy nutrition, strict cleanliness, and outdoor sunshine. For a hand-fed child under one year, fresh milk, with about one-third lime-water or barley-water added; older children might be given cod-liver oil, iron, the hypophosphites, pounded mutton, poached eggs, also galvanism might be used. The surgical methods necessary were also ably brought out in these papers.

THIRD DAY—JUNE 9TH.

DR. ELI H. LONG, of Buffalo, read a paper on the "Physiology of the Respiratory and Circulatory Changes at Birth, Relating to Asphyxia and Its Treatment." The paper was carefully prepared and well given, and contained many points of interest.

DR. A. HAZELWOOD, of Grand Rapids, Mich., read a paper on the "Prevention of Scarlet Fever." He favors the cottage-hospital plan of treatment on a large tract of land outside the city, where mother and child could both go, as the only way to solve the difficulty of isolation.

DR. VAUGHAN, of Ann Arbor, Mich., believes that the scarlatinal microörganism is distributed throughout the individual, and that in all cases the kidneys are affected, as the poison is eliminated by that route. The accumulation of the poison is dangerous to life. Dr. Vaughan employs elaterium and pulvis jalapi compositus. Pilocarpine is seldom to be used on account of the depression to which it gives rise. Hot or dry baths are to be preferred. The premises on which there have been cases of scarlatina should be disinfected with sulphur (three pounds to every thousand cubic feet), and washed with mercuric chloride (1 : 2000). Quoting from memory, Dr. Vaughan gave the following statistics: The average number of deaths from scarlet fever in Michigan was formerly eight hundred per annum; now it is two hundred. Formerly there were ten cases to each outbreak; now there are only two. These changes are largely due to acquired immunity, more thorough disinfection, and isolation.

DR. BRUSH closed the discussion by reading an interesting paper on "Scarlet-fever Contagion."

The meeting was closed by the reading of one of the most interesting papers of the session by DR. W. A. DIXON, of Ripley, Ohio, entitled "The Morbid Proclivities and Retrogressive Tendencies in the Offspring of Mulattoes," in which he contended that the children of mulattoes are the subjects of constitutional diseases to a much greater extent than are those of unmixed blood. Dr. Dixon's paper will be published in a future number of THE NEWS.

SECTION ON MATERIA MEDICA AND PHARMACY.

FIRST DAY—JUNE 7TH.

The Section was called to order by the Chairman, DR. FRANK WOODBURY, of Philadelphia. In the absence

of the Secretary, DR. WHELPLEY, of St. Louis, DR. F. E. STEWART, of Wilmington, Del., was appointed Secretary *pro tem.*

In the address of the CHAIRMAN, attention was directed to the evident disposition of the Association to devote more time to scientific work, and thus greatly increase the usefulness of the sections. A peculiar feature of the Section on Materia Medica and Pharmacy, is that the Association has formally invited the American Pharmaceutical Association to be represented by delegates who shall participate in its scientific work. This recognition of the high standing of representative pharmacists is a just tribute to their professional attainments, and establishes pharmacy as a department of medical science. This is a consummation of immense value to both medicine and pharmacy; and, that we have been able in any way to assist in bringing it about, should be a subject of congratulation. Its consequences upon the development of pharmacy in this country must be great and far-reaching. Biologic chemistry and practical pharmacy are closely related and should be studied together. The present aspect of medicine, speaking from the therapeutic standpoint, is largely chemical, and is mainly based upon chemical ideas. Indeed, we might almost represent health by a very complex chemical formula, graphically written, so as to express exact molecular composition. Various modifications and substitutions may take place, representing departures from the normal, more or less marked and corresponding with certain diseases or diatheses. While the researches of bacteriologists have revealed specific microörganisms characteristic of different infectious diseases, later observations serve to establish the fact that these so-called disease-germs do not so much cause disease directly by their numbers as they do so indirectly by their chemical products, which enter the blood and act as toxic agents. The important relation of pharmacy to medical practice is that it supplies chemical substances capable of acting as antidotes to the poisonous action of these agents.

DR. A. B. PRESCOTT, of the University of Michigan, read a paper on "Caffeine and the Question of its Isomerism." He considered the various caffeine-bearing plants from chemic and physiologic standpoints, and demonstrated that the fact of isomerism had not been established. Caffeine is a substitution-derivative of xanthine, the former being chemically a trimethyl-xanthine. The effects of various beverages from caffeine-bearing plants are modified by the presence of other substances, such as tannin, volatile oil, etc., caffeine not entirely producing the physiologic effects of tea or coffee.

PROF. REMINGTON called attention to the scientific foundation for the custom of simply making an infusion of tea, by which the flavoring substances and caffeine are extracted, leaving the more insoluble tannin behind.

The CHAIRMAN stated that if the statement is to be accepted that theine is different from caffeine, it will be necessary to write "theæ" after caffeine, since much of the supply of caffeine is obtained from damaged tea. Dr. Edward R. Squibb, in a letter some years ago, declared that there was no difference between theine and commercial caffeine, and threw some doubt upon the existence of caffeine, as such, in the living plant. A practical point, showing that tea is prized for something more than its alkaloidal content, lies in the fact that some cheaper grades of tea are richer in caffeine than the higher-priced teas. As regards the difference alleged to exist between the alkaloid derived from tea and that from coffee, it is possible that some of the volatile substances of the tea are not fully separated from the caffeine, and modify its physiologic action; just as piperine may owe much of its stimulating qualities to volatile substances usually associated with it.

In practical medicine, the insolubility of tannin should be remembered, and in making infusions for the astringent effects, as in antimonial poisoning, or for their action on mucous membranes, the tea or coffee should be boiled. On the other hand, when the stimulating effects alone are desired, a rapid infusion is all that is needed.

In the absence of DR. E. L. PATCH, of Boston, his paper on "Examination of Market Fluid Extracts" was read by title.

A paper on "Pharmacy at Health-Resorts," by DR. F. E. STEWART, was also read by title.

PROF. JOSEPH REMINGTON, of Philadelphia, read a paper entitled "Prescription Exigencies," which was highly practical and interesting, and led to a general discussion.

SECOND DAY—JUNE 8TH.

The discussion on the Revision of the United States Pharmacopeia was opened by PROF. JOSEPH REMINGTON, of Philadelphia, a member of the Committee on Revision. He stated that the Pharmacopeia is rapidly approaching completion and that much of it is already in type. It is believed that the work will appear before the end of this year. Some important changes have been made, the most notable being the adoption of the metric system in the formulæ. The hope was expressed that this change would be approved and supported by the members of the Section.

A general discussion followed, in which PROFS. PRESCOTT, BEDFORD, LONG, DR. CLARKE and others participated.

The CHAIRMAN opened the discussion on "An International Pharmacopeia." He stated that the adoption of an international pharmacopeia has been under consideration for a number of years. The present seems a particularly propitious time for renewing the agitation. Americans read English and Continental medical journals and books, and extracts from these, containing formulæ, are constantly reappearing in American journals and text-books. As there are marked differences in strength among different products bearing the same name (such as tincture of belladonna), and as even the ounce of water is not the same in the British and United States Pharmacopeias, an international comparative commentary upon the different pharmacopeias, containing the principal drugs in use by civilized nations, with their preparations, seems necessary. Such a work would be most convenient for reference, both for physician and pharmacist.

A series of resolutions was offered thanking the Committee on Revision for their valuable labors upon the Pharmacopeia, and requesting that in all doubtful questions coming up for decision preference should be given to those that would facilitate the creation of an inter-

national pharmacopeia. The resolutions were unanimously adopted. The subject was approved and made the order for discussion upon the second day of the session at the next meeting.

THIRD DAY—JUNE 9TH.

The following papers were read by title: "Europhen," by DR. J. V. SHOEMAKER, of Philadelphia; "Tablet Triturates and Dosimetric Granules," by DR. WM. F. WAUGH, of Philadelphia; and "Notes on Therapeutic Novelties," by DR. I. N. LOVE, of St. Louis.

The Business Committee of the Section was elected as follows: Dr. Horatio C. Wood, of Philadelphia; Dr. F. E. Stewart, of Wilmington, Del.; and the Chairman of the Section.

Dr. F. Woodbury was reëlected *Chairman*, and Dr. F. E. Stewart was elected *Secretary*.

SECTION ON PHYSIOLOGY AND DIETETICS.

FIRST DAY—JUNE 7TH.

An anticipated projection of illustrations of foods on the screen, by the Secretary, was postponed owing to the lack of solar light.

It was next moved and seconded that the sense of the Section should be formally passed upon the pending bill in Congress on "Food and Drug Adulterations," following a discussion by a more general meeting, and if possible the officers of the Association to be present.

SECOND DAY—JUNE 8TH.

PROF. C. H. A. KLEINSCHMIDT, of Washington, D. C., Chairman of the Section, read an important paper on the past year's progress in the "Physiology of the Nervous Centers." This lengthy *résumé* included the results of the more recent work, pathologic and clinical, done by European and American investigators. It considered the advances in the anatomy of the origin of the cranial nerves, the discovery of new reflexes and functions of facial motor nerves, the belief now of physiologists that all nerves are trophic, Courmount's theories regarding the functions of the cerebellum, and Richardson's theories, the chemico-physiologic theories of combustion, the action of the central nervous system.

The attractive theory of Pryor, that sleep is due more or less to a decline of destructive metabolism, received full mention, and that clinically insomnia is best treated by restoration of the balance of proper nutrition of the nerve-centers. The many recent advances in cranial-nerve origins is vastly modifying former views of the functions of the bulbar bodies, nerves of sight, and the motor nerves of the face.

The phrenic nerve is now found to be, not a purely motor nerve, but a mixed nerve; and the cervical and spinal sympathetic systems of nerves contain trophic fibers. In fact, it may be said that physiologists are coming to the view that nerve-structures and nerves cannot be so sharply divided into motor and sensory as formerly, but that all nerves are trophic and capable of both motor and sensory functions.

Brain-localizations and the progress made by Horsley and Schaefer, leading uniformly to like conclusions, were noted.

Brown-Séquard's observation that analgesic effects can be produced on wounds in any part of the body (in dogs and monkeys) lasting some days, by stimulating the laryngeal mucosa, was mentioned as being of possible clinical use in the case of man.

Among the new reflexes is one by Knapp, whereby stimulation of the back of the wrist is attended with contraction of the levator menti of the same side.

The vomiting center is proved to be located in a space five millimeters in front of the calamus scriptorius and in the deeper part of the medulla. This fact must dispose of many old theories, and demonstrates that most nerves are capable of many functions, for in this case it is merely the respiratory center acting as a vomiting center.

Among the many new and startling theories must be mentioned that of Courmount on the functions of the cerebellum. This is based upon clinical observations purely, and has attracted the great and favorable interest of Forel, who has twice recently reviewed it. This theory throws much doubt upon our former belief that the cerebellum is simply an organ of coördination. Courmount credits it with other and more important functions, upon the clinical evidence alone.

Mendel's work on the facial nerve-supply must in time undermine most of the present conceptions of facial innervation and functions of important organs.

All action of the central nervous system, according to Richardson, is due to chemico-physiologic action or "combustion"—(*a*) the slow combustion in the cerebro-spinal axis, and (*b*) the more obvious combustion in the so-called working organs represented by animal heat. The gray matter is the seat of a slow combustion, and the white matter supplies the combustion-material. The cerebro-spinal fluid has the most important function, because it is the most condensed fluid of the cerebro-spinal axis, which is not only the center for the reception of external impressions, but a true chemical and dialyzing center and the center of static combustion.

SURGEON C. A. SIEGFRIED, United States Navy, read a paper on "The United States Navy Ration," giving the history of the food-supplies and methods in use from revolutionary times to the present, the various exigencies and requirements of naval seamen's dietaries, the character of their muscular work, and the nutrient and dynamic values of the present navy rations. The scales of food-supplies included that for naval apprentices, the regular seamen, and the punishment diets. He would divide a ship's dietary into the three classes of moderate workers, hard workers, and severely hard workers, the latter to receive as much as 210 grams of protein, 175 of fat, and 650 of carbohydrates; and the other extreme, the moderate workers, Prof. Atwater's scale (or standard American) of 125 grams each of protein and fat and 500 of carbohydrates. The average modern war-ship's company is composed of 10 per cent. moderate workers, 65 per cent. hard workers, and 25 per cent. severely hard workers—firemen, etc. Greater satisfaction could probably be secured in naval rationing if the common adaptations and economic methods in use in some foreign navies were applied in ours, and the food-supply were graded according to work, climate, season, etc. On the whole, the United States Naval ration, while superior to any other naval ration in dynamic or potential energies, is still below that of the well-paid mechanic or laborer ashore, and could be easily improved upon. The common

experiences the world over exist in the navy regarding waste in preparation and cooking, and no more or greater service could be done "Jack" than by training for him competent cooks. The United States Navy ration is commuted at thirty cents per diem, and the boys coming into the service are subsisted by purchase, and consume about 18 per cent. more nutrients for this sum than can be calculated for the regular ration issues. The paper contained many tables of obvious value, the fruits of long labor.

The paper on "The Army Ration," by ASSISTANT SURGEON CHARLES E. WOODRUFF was, in the absence of the writer, read by the Secretary of the Section. It was a long and painstaking review of the present customs in the army, the many difficulties and trials under which army authorities work, and a detailed analysis of the food-supplies consumed by a body of troops at a Western outpost for a period of ten days. There has not been much change in the army ration for many years, and in the absence of careful company and commanding officers the soldiers may at times lack a proper or varied enough dietary. These defects are remedied in most cases, however, by good management, company gardens, and efforts in the direction of good cooking. A garrison post may, in the instance of a desert or barren location, be poorly nourished, and in another luxuriously, owing to the possibilities of a good garden. It is, however, plain that something could be done both for our soldiers and sailors, notwithstanding that in recent years much improvement has been made in their food-supplies. This contribution should be put in the hands of every army officer, containing, as it does, so much of valuable and pertinent detail of actual customs, and the ways and obvious means so clearly pointed out for their improvement.

The Association has thus, in permanent form, full and detailed information regarding the subject of dietetics of our army and navy, and the scientific data concerned, in the most satisfactory manner.

"The Methods, Quality, and Quantity of the Component Parts of the Marine-Hospital Service Food-supplies" were given in a paper by Dr. G. W. STONER, but these, being ample and the common daily marketings and of fresh supplies, call for no extended notice.

THIRD DAY—JUNE 9TH.

The subject of the Paddock "Food and Drug Adulteration Bill" was taken up, and, being discussed, was most heartily recommended for enactment as being of vital importance to the health and well-being of our people.

The subject was transmitted to the Section on Materia Medica and Pharmacy for consideration.

The following papers were read by title, the writers not being present:

"Diet in Its Relation to the Treatment and Prevention of Disease," by Augustus P. Clarke, Cambridge, Mass.; "The Relative Interdependence of Organs in Health and Disease," by H. J. Herrick, Cleveland, Ohio; "Food and Hygiene of Old Age." by J. M. French, Milford, Mass.

Obituary.—Sir Wm. Aitken, Professor of Pathology in the Army Medical School at Netley, is dead, at the age of sixty-seven years.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fourteenth Annual Meeting, held at Boston, Mass., June 20, 21, and 22, 1892.

DR. S. W. LANGMAID, of Boston, delivered the President's Address. He made touching reference to the loss of Dr. Donaldson, of Baltimore, and of Sir Morell Mackenzie—the former a Fellow, the latter an Honorary Fellow, of the Association. He reviewed the rapid advance made in laryngology within a few years, since it took a prominent position among the specialties in medicine. Such advance will be greatly helped by faithful adherence to this Association. Companionship with fellow-workers is necessary to completeness of one's growth. Membership is not only a means of information, but it also acts as a stimulus to work. Dr. Langmaid expressed the hope that the next ten years will show such work that American laryngology will occupy the position that has always been accorded it, namely, the first in merit as well as priority of establishment.

DR. D. BRYSON DELAVAN, of New York, read a paper on "The Influence of Certain Diathetic Conditions upon the Prognosis in Operations upon the Throat." He called attention to the importance, before operating upon the throat, of searching for the existence of a diathetic condition that might influence the result of the operation, such as the strumous, the rheumatic, and the hemorrhagic, and exophthalmic goiter, and general lymphadenoma. In the case of the two last mentioned, the removal of enlarged tonsils and of adenoid hypertrophy at the vault of the pharynx is attended with no extraordinary risk.

In strumous cases, complete removal of the offending tissue is more difficult, recovery is slower, and recurrence is more probable. The earlier, however, the cases are operated upon the better.

In rheumatic cases no special difficulties are offered, and the prognosis is most brilliant.

The hemorrhagic diathesis is the most important, because the most dangerous. Its presence contra-indicates all surgical interference. The only known accidents that have happened in this country in the removal of adenoid hypertrophy at the vault of the pharynx have been in hemophilic subjects. Adenoid enlargements are unusually common in these patients. There is no method of operating upon them, now known, that is safe. The galvano-cautery is not a reliable hemostatic, even in ordinary cases, as bleeding, both immediate and secondary, may occur after its use. As many of these cases urgently require relief for their throat-troubles, it is most desirable that a method of reaching them more satisfactory than any heretofore practised be devised.

DR. S. HARTWELL CHAPMAN, of New Haven, read a paper entitled "Some Pathological Conditions of the Upper Air-passages Coincident with Attacks of 'La Grippe.'" He reported sixteen cases of more than ordinary interest, selected from a large number of cases of influenza complicated by secondary affections of the upper air-passages. Eight were cases of spinal disease; one, a case of diabetes insipidus; four, cases of renal disease; three, cases of rheumatic gout.

The onset of "la grippe" was quite similar in all

of these cases: headache, nausea, anorexia, flying pains, exhaustion, progressing to extreme malaise; moderate fever, pulse either considerably accelerated or greatly retarded, mild delirium, pain and stiffness in the back. There is a close similarity between these symptoms and those of the milder forms of epidemic cerebro-spinal meningitis.

One of the rheumatic cases presented laryngitis crouposa, complicated by broncho-pneumonia; two, aphthæ of the mouth and pharynx, extending to the brim of the larynx.

The four cases of renal disease presented sanguineo-purulent naso-pharyngeal inflammation, associated with acute tonsillitis and sympathetic enlargement of the cervical glands. The swelling of the tonsils became so great as to threaten suffocation, and was relieved by incision.

In some of them there was hemorrhage, but not of dangerous character; in one, croupous laryngitis. The duration of the naso-pharyngeal inflammation was about two months; of the laryngitis, only four days.

In the case of diabetes, there was intense congestion of the entire pharynx and edema of the larynx, which continued for eight days and markedly interfered with breathing. During the severest period of the disease the pulse, which previously had been frequent, fell to 70, and the patient was less nervous.

In one of the eight cases of spinal disease, with kyphosis, a form of paralysis developed that had been absent for many years; and during the attack the pulse, normally 80, was reduced to 50. The spinous processes were intensely sensitive. In three cases of curvature of the spine in females the attack of influenza was not severe; but in all there was reduction in the rate of the pulse, extreme malaise, and sensitiveness of the spine. Secondary affections were aphonia and purulent naso-pharyngeal inflammation.

DR. FREDERICK I. KNIGHT, of Boston, read a paper on "Pharyngo-mycosis." Ever since special attention has been paid to disease of the throat, he said, observers have been struck by the peculiar obstinacy of chronic folliculitis of the tonsils, not infrequently accompanied by a similar condition at the base of the tongue, and occasionally on the arches of the palate and of the pharynx. The affection presented whitish, yellowish or grayish exudations situated at the mouths of the follicles, sometimes cheesy and easily removed, sometimes cretaceous, and sometimes only tough and stringy, and running deeply into the follicles. Speedy recurrence follows removal of the products, even after the subsequent application of strong medicaments. Fraenkel, in 1873, pointed out an abundance of leptothrix threads in such products, and some writers have looked upon the parasite as the cause of the condition. A number of other forms of parasitic growths in the throat have also been described. Other observers, notably Chiari, believed that the parasite is simply an accidental complication.

In the treatment of typical cases of mycosis nothing has been found satisfactory except boring deeply into each follicle with a galvano-cautery point. If any of the disease were situated in a part of the tonsil that could be removed, excision would shorten the treatment.

DR. DELAVAN stated that he had obtained the best results from frequent washing with borax or with mercuric chloride, and, above all, by correcting disturbed digestion.

DR. DEBLOIS, of Boston, stated that he uses instrumental means, and a mild astringent, such as nitrate of silver, and gives attention to the digestion.

DR. JOHNSON, of Baltimore, stated that he found these cases mostly among debilitated school-children and old subjects. He uses local and constitutional measures.

DR. CHAPMAN advised treating these cases locally, with fuming nitric acid, introduced through a grooved platinum needle, and internally by nitro-muriatic acid.

DR. JONATHAN WRIGHT, of Brooklyn, reported "A Case of Fibrous Epithelioma at the Root of the Tongue." The diagnosis was extremely difficult. The form in which the disease presented itself was rare. When first examined, the tongue seemed normal, except for two prominences on each side at the base, which felt hard and firm. Grave doubts were entertained as to the exact nature for several months; finally, Dr. McBurney operated for carcinoma. An ulcer had formed, making the diagnosis more evident. The patient did well for a time, but finally died, without, however, a recurrence.

DR. BEVERLEY ROBINSON, of New York, read "A Report of Some Cases of Membranous Sore-throat." In the three cases reported there was great difficulty in diagnosticating between true diphtheria and membranous sore-throat of some other origin. The bacteriologic examination failed to disclose the presence of the Loeffler bacillus, while streptococci were present in abundance. Failure to find the Loeffler bacillus, however, does not necessarily disprove the existence of diphtheria. In case of doubt it is unwise to prematurely make a diagnosis of true diphtheria and cause the family alarm and trouble. At the same time certain precautions could be taken against unnecessary exposure of the well. Sulphur-fumigations are especially objectionable. The treatment might be that which would be adopted in a case of true diphtheria. Dr. Robinson spoke highly of the use of powdered cubebs, taken by the mouth in small pinches at frequent intervals. He condemned the custom of the health-officers in some sections of posting houses with diphtheria, as if persons passing such houses and not entering them were liable to take the disease.

Considerable discussion followed, and a resolution was adopted making as a subject for discussion at the next annual meeting, "The Best Means of Protecting the Public against the Spread of Diphtheria."

DR. MORRIS J. ASCH, of New York, presented a tampon, consisting of a hard-rubber tube, with perforations, for use after operations for deviation of the nasal septum. Dr. Asch also presented a set of Dr. Dessau's antiseptic electrodes, and Dr. Dessau's curette for adenoid growths.

DR. D. B. DELAVAN, of New York, proposed the administration of potassium iodide, in peptonized milk, in cases of tertiary syphilis of the throat, in which the ulceration had become so severe that the patient could not swallow with ease.

DR. J. WRIGHT, of Brooklyn, presented an improved forceps for the removal of adenoid growths in the post-nasal space.

DR. JOHN O. ROE, of Rochester, presented an improved Adams's forceps for straightening the nasal

septum, which possessed the advantage of enabling one to over-correct the deformity.

DR. C. H. KNIGHT, of New York, showed an improved snare for removal of the tonsils with a ring-safeguard.

DR. C. H. KNIGHT, of New York, read a paper entitled "Intubation for Chronic Stenosis in a Boy of Ten." According to the statement of his physicians, the boy had been ill for a week or more with dyspnea, aphonia, cough, and fever. There was a history of bad hygiene and poor diet. He could not whisper, and his breathing was quite noisy and labored. The dyspnea was decidedly more marked at night; it was relieved by inhalations of oxygen. The boy's condition grew worse. On examination a neoplasm was found beneath the vocal bands. The bands were red, and did not approximate on phonation. Beneath the cords, extending along their entire length and invading the anterior commissure, was a mass of tissue, paler in color than normal mucous membrane, having an uneven, and at certain points an almost papillary surface. No ulceration could be discovered. The air-passage was converted into an irregular, narrow slit. To relieve the dyspnea an O'Dwyer tube was introduced. This was worn intermittently for many weeks. It was impossible to get sufficient of the tissue to make a satisfactory microscopic examination. The process was at first thought to be tuberculous, but the absence of pulmonary signs and the marked change for the better after intubation pointed to simple subglottic papilloma. After about three months tracheotomy, thyrotomy, and radical extirpation of the neoplasm were proposed, but the case progressed rapidly to a fatal termination from general tuberculosis.

The points of interest were: 1. The simplicity of intubation as compared with tracheotomy, and the ease with which the tube was extracted, with the aid of cocaine and under the guidance of the mirror. 2. The slight amount of disturbance excited by the presence of the tube, and the absence of objection to its prolonged retention. Finally, the question suggested itself: Was it a case of primary laryngeal tuberculosis? The patient seemed much more comfortable than he could have been with the tracheal instead of the laryngeal tube.

DR. ALEXANDER A. MACCOY, of Philadelphia, read a paper entitled "Rare Forms of Laryngeal Growth," reporting a case of myxoma, and one of fibroma of the larynx. The first is quite rare; the second is not so infrequent. The myxoma seemed to have had its origin from the margin of the orifice of the ventricle. The patient's voice was completely restored after removal of the growth. In the other case most of the growth was removed by the cold snare, the remainder to be operated upon later. The tumor appeared to have sprung from the anterior and right surface of the arytenoid cartilage.

DR. H. L. SWAIN, of New Haven, reported "A Case of Tumor of the Larynx," relating the history of a case of fibro-myxoma of considerable size, attached by a pedicle to the anterior commissure of the vocal bands. The growth, the base of which was spread out over a greater surface than had been supposed, was removed with difficulty. Its removal had been followed by relief of the difficulty connected with phonation and respiration, and the patient had for two years remained free from recurrence.

DR. C. C. RICE stated that he has found it easier to apply the guillotine snare than the forceps in the removal of small laryngeal growths. Recently, in the case of a policeman, he had observed syncope follow the use of 4 per cent. solution of cocaine in the throat.

DR. LANGMAID stated that, on the recommendation of a European authority, he had used nicotine in an operation for the removal of a growth in the larynx in one case, and threatening poisonous symptoms developed.

DR. C. C. RICE, of New York, read a paper on "The Value of Sprays in the Treatment of Catarrhal Affections of the Upper Air-passages." He does not recommend the spray as a substitute for other methods of treatment. While some advantages attend the use of petroleum preparations, there is danger in their inconsiderate use, as a dry condition of the nasal passages may result. Such agents as iodoform and aristol lose much of their antiseptic property when used with oily agents, nor when thus used could their stimulating action be so well relied upon. In catarrhal affections of the upper air-passages nice judgment is required in selecting the drug, and particularly the strength of the solution to be used as a spray. The pressure should be regulated and the temperature should be adapted to the particular case. A weak solution of cocaine, say less than 1 per cent., is, perhaps, as good an astringent as any. A pressure of fifteen pounds to the square inch is sufficient for the anterior nares, while a pressure of from twenty-five to thirty pounds is necessary for a post-nasal spray.

DR. J. W. FARLOW presented a form of adenoid forceps which he had purchased in Paris, and had found an excellent instrument for the removal of adenoid growths in children and adults.

DR. JOHN O. ROE, of Rochester, read a paper on "The Correction of Deformity Resulting from Abscess of the Nasal Septum." In the case detailed there was, as is usual in these cases, marked thickening and widening of the dorsum of the nose proportionate to the amount of flattening. This thickened ridge of tissue was incised on both sides a short distance from the septum, at a point where it thinned into the alæ. The incision was made along the edge of the flattened tissue, through the cartilage of the alæ, to the under side of the skin, care being taken not to wound the latter. The skin was raised from the dorsum of the nose, and the flaps then turned upward and held in place by small ivory spring-plates on each side, having holes through which sutures were passed from one to the other, extending through the flaps. These threads were then tied so as to hold the flaps firmly in place, care being exercised not to strangulate the parts. The flattened condition of the nose was relieved, but not entirely. Owing to the entire absence of the triangular cartilage, there was not sufficient support to hold the nose upright. In order to increase the solidity of the septum, each side of the lower portion of the septum was first scarified, the front portion of the skin, however, being left intact. Wide, thick flaps were cut from the floor of the nostril opposite the portion of the septum which it was desired to render more rigid. These were turned upward and fastened together with clamps in the same way as the upper flaps.

The upper border of the flaps was also connected to the cut portion of the septum by means of fine sutures. The result was excellent. To maintain the nose in position until the parts healed, a small spiral spring was used.

DR. T. A. DEBLOIS, of Boston, read a paper on "The After-results of Nasal Cauterization." He related the histories of five or six cases in which he or others had cauterized the nose two or more years previously. In most of them the cauterization had been practised for an hypertrophied condition of the turbinated bone, and the immediate result, as far as relief of the symptoms was concerned, had been successful. Two years subsequently the patients had returned, again complaining of nasal obstruction. In some a rhinoscopic examination revealed, on either side of the original scar left by the cautery, the presence of swollen and projecting mucous membrane, which blocked up the nasal passages. In one case—a somewhat remarkable one—the mucous membrane, which was thrown in corrugated folds, had been cauterized frequently. Some of the cases showed, and doubtless many others would show, that the cautery may fail of the desired effects as a result of improper application, such as, on the one hand, making the scar-tissue too deep or, on the other, making it too shallow, and again of including in it too much tissue or not enough.

DR. J. H. BRYAN, of Washington, reported "A Case of Suppurating Ethmoiditis." The patient gave a history of having suffered from caries of an upper molar tooth. Her nose became closed; the secretions, at first watery, became thick and fetid. There was pain over the bridge of the nose, extending along the infra-orbital ridge to the temporal region. There were severe headache, pain on pressure of the eyeball, and a crepitating sensation below the orbit. On the left side of the nose were two mucous polypi attached to the anterior extremity of the middle turbinated bone. After snaring off the polypi, thick caseous secretion was observed to come from both the middle meatus and from above, between the middle turbinated body and the septum. Examination with the electric light showed the left antrum to be opaque, indicative of inflammation of the ethmoid cells. In spite of treatment, the conditions grew worse, until the abscess spontaneously discharged a large quantity of thick caseous secretion. After this the pain ceased and the general health improved.

The following are the officers for the ensuing year:

President.—Dr. Morris J. Asch, of New York.
First Vice-President.—Dr. S. Johnston, of Baltimore.
Second Vice-President.—Dr. J. C. Mulhall, of St. Louis.
Secretary-Treasurer.—Dr. C. H. Knight, of New York.
Libarian.—Dr. T. R. French, of Brooklyn.
Member of Council.—Dr. S. W. Langmaid, of Boston.

The next meeting will take place in New York in the last week of May, 1893.

CORRESPONDENCE.

THE LATE D. HAYES AGNEW.

To the Editor of THE MEDICAL NEWS,

SIR: At the request of Mrs. D. Hayes Agnew, I am preparing a biography of her late distinguished husband; in consequence, I am looking for data on this subject. Will you kindly announce that I am desirous of obtaining from all of Dr. Agnew's former friends, colleagues, associates, students, and acquaintances all authentic data in any way relative to his career or character? Dr. Agnew's acquaintance was so vast, and his life was so actively spent among his friends, while his own modesty was so marked, that undoubtedly a great many incidents, anecdotes, characteristic stories, etc., are unknown to his family. All material, however apparently insignificant or small, will be welcomed. Credit will be given to all data which is used. Yours faithfully,

J. HOWE ADAMS.

252 SOUTH SEVENTEENTH ST.

CHAIRMEN OF COMMITTEES OF ANATOMIC AND BIOLOGIC NOMENCLATURE: CORRECTION.

To the Editor of THE MEDICAL NEWS,

SIR: In a circular relating to "American Reports upon Anatomical Nomenclature," issued last winter by me as Secretary of the Committee of the Association of American Anatomists, in the third paragraph of the third page, the name of the Chairman of the Committee of the Anatomische Gesellschaft should have been Prof. A. von Kölliker, and that of the Chairman of the American division (appointed in 1891 by the American Association for the Advancement of Science) of the International Committee on Biologic Nomenclature should have been Prof. G. L. Goodale. I exceedingly regret the occurrence of the errors, due in the one case to my own misapprehension, and in the other to a clerical mistake.

BURT G. WILDER, M.D.

CORNELL UNIVERSITY, ITHACA, N. Y.

NEWS ITEMS.

"The Scalpel" is the name of a new monthly publication issued from the College of Physicians and Surgeons of Chicago, and under the editorial care of Dr. Louis J. Mitchell, assisted by two members of the class. Ventures of the kind of which this is an illustration are to be heartily encouraged as an indication of a progressive tendency, with which, however, the publication of an advertisement of a secret nostrum on the second page of the cover is entirely out of harmony.

The Lehigh Valley Medical Association will hold its twelfth annual meeting at Bethlehem, Pa., on Thursday, July 7, 1892. Dr. John B. Deaver, of Philadelphia, will deliver the annual address, the subject of which will be "Inflammation of the Right Iliac Fossa Associated with Lesions of the Cecum, the Vermiform Appendix and Adjacent Tissues."

Medico-Chirurgical College.—Dr. W. F. Haehnlen has been elected Professor of Obstetrics; Dr. W. E. Ashton, Professor of Gynecology, and Dr. C. M. Seltzer, Professor of Hygiene.

Dr. John Ridlon, formerly of New York, has been appointed lecturer on Orthopedic Surgery at the Chicago Medical College.

CLINICAL OBSERVATIONS AND RESULTS OF ELECTROLYTIC ACTION IN ESOPHAGEAL STRICTURES.[1]

BY DONALD S. CAMPBELL, B.A., M.D.,
OF DETROIT, MICH.

IN the early summer of 1888, at the meeting of the State Medical Society, held in Detroit, I briefly reported before the surgical section the successful cure, by electrolysis, of a case suffering from tumorous stricture of the esophagus. In May of the same year, at Cincinnati, before the surgical section of the American Medical Association, I clearly demonstrated, from a goodly number of tabulated cases, the great advantage of this powerful agent over other procedures in the removal of various neoplastic structures occupying the nasal, pharyngeal, and laryngeal regions; but up to that time no more interesting case presented itself to our observation than the one reported.

It will be remembered that the report caused considerable sensation in medical circles at the time, not so much from the exhibition of the patient herself—who, nevertheless, was a living monument of the practicability of the galvanic current—nor from the history or clinical facts brought out in the general discussion, but from the practical results and the novelty of the treatment employed. Indeed, it is not to be wondered at, especially when we consider the location and extent of the fibroid-tissue processes, involving, as they did, the greater portion of the middle part of the gullet, and which up to this time had defied every deliberate attempt at removal—to succumb at last to an agency so simple and painless, and comparatively harmless in the hands of one possessing knowledge of its application, yet powerful enough to induce destructive changes in their cell-like structures so as to produce their absolute destruction by absorption, thereby restoring the long-lost functional activity of the esophagus. Though nearly five years have elapsed since the woman first submitted herself to electric treatment, as a hopeless, physical wreck—from simple starvation—she is well in every respect to-day, not a symptom being present to indicate recurrence of the growth, thus proving conclusively the permanency and reliability of the treatment.

[1] Read before the Section of Surgery and Anatomy of the American Medical Association, June 7, 1892.

Since then I have added to the list six other successfully treated strictural cases, which I am about to report. These fully establish the claim that I made on that occasion, that no procedure has yet been presented which is as capable of combating the difficulties with as much safety and reliability as the influence of the galvanic current.

I do not, on this occasion, propose, however, to weary you with any "reiterated logic" on the subject matter, but to present actual clinical facts from carefully tabulated notes, so as to estimate as far as possible the value of the treatment employed. It is, nevertheless, well to bear in mind that the use of the galvanic current directly applied to any portion of the gullet was considered hazardous, owing to the close proximity of the pneumogastric nerve, until I clearly demonstrated from the first reported case, four years ago, that it was otherwise if the strength of current were intelligently regulated. Indeed, I remember well the admonitions which the late Sir Morell Mackenzie, of London, and Dr. Louis Elsburg, of New York, gave me several years ago for just attempting to broach the term electrolysis as a means of combating these abnormal conditions. They fully concurred in the belief that galvanism, however mildly applied to the esophagus, would be attended with danger, though they were aware that it had been employed with safety and good results to general neoplastic matter situated in the immediate vicinity of other vital parts, showing that even at that time, ten years ago only, they were entirely ignorant of the genuine chemical absorption of galvanism and the safeness with which it could be applied in close proximity to important nerve-centers, without disturbing their functions, even after a thorough knowledge of its behavior was obtained. Since then, however, we have made rapid strides in the general use of the galvanic current, and thoughtful study of its dosages in diseased tissues wherever situated. Indeed, the clouds of empiricism have gradually swept by, and though much yet depends on experience gained by experimentation, we can see clearly ahead, by the deep insight that enables us by our present knowledge of its subtle laws, to understand its hidden scientific meaning, and apply it accordingly.

Since it is the object of this paper to report in detail the several esophageal strictural cases that happened to have come under my notice, it will be in keeping with the subject to abstain at present from giving

the history of the development of the application of galvanic electricity and the scientific explanation of its operations. Neither do I propose to deal with the pathology of varied strictural abnormalities, but I shall simply present clinical facts as I carefully noted them while the several patients were under treatment. The first case then to which I shall refer is:

CASE II.—Mrs. H., a well-to-do lady of seventy years, a resident of Detroit, consulted me three years ago last Jannary for increasing dysphagia, after having gone the rounds of several physicians, from New York to Omaha. She stated that several years previously, having drunk in a hurry a very hot cup of tea, she experienced at the time, and for several weeks afterward, considerable pain and difficulty in swallowing solid food. This gradually subsided until she thought herself as well as usual, when to her great astonishment, six months after this unavoidable accident, she realized that the lumen of her gullet was gradually getting smaller. Though she experienced no pain, she began to find some difficulty in swallowing solid food. This dysphagia gradually increased from year to year, though dilatation was frequently practised, until she was induced to consult me, when I learned that she had not been able to swallow solid food at all for several months previously, and it was with difficulty that she could swallow even fluids. Indeed, she was delicate, very anemic and emaciated from want of nourishment, but was willing to try any treatment to obtain relief.

After obtaining the foregoing history I made a careful examination of the gullet, and, after much annoyance, particularly from retching, found that she was suffering from what I considered a fibrous stricture, an inch in length, situated about two inches below the cricoid cartilage. It was with great difficulty that I managed to pass a No. 6 (English gauge) esophageal bougie. After gaining an entrance, I resolved to try gradual dilatation again. After several weeks of faithful trial I abandoned it as a useless procedure in her case, for the irritation it developed appeared to increase the localized occlusion. I then concluded to try electrolysis. On January 28, 1889, an esophageal electrode, one quarter inch in diameter by half an inch in length, was introduced down to the commencement of the obstruction, where a current-strength of five milliampères was administered under gentle pressure. As no inconvenience was experienced, I gradually increased it to ten milliampères; and though decided impressions of the current were manifest, it passed easily by the stricture in sixteen minutes, without causing any excitement on the part of the patient. This same electrode was introduced again on the 31st of January and on February 3, when I resolved to try to pass an electrode, half an inch by one inch in length. This was accomplished, after several attempts, on the 12th of February, with a current-strength of fifteen milliampères. By this time she realized that a change for the better was occurring, for she could swallow fluids much better and partake of thick gruel. This electrode was introduced again on the 18th and 25th, and March 6th, when it was dispensed with for a larger one of five-eighths of an inch by one and one-fourth inch in length. This esophageal electrode was very easily made to pass the obstruction, and was only used twice, viz.: on the 10th and 15th of March; for the stricture appeared to yield to the slightest pressure, though even now she was not able, or rather I should say willing, to swallow solids. The last and largest electrode I used to electrolyze the stricture was one inch in diameter by two inches in length. It was applied in all ten times, for about ten minutes' duration, and under a current strength of twenty milliampères. But it was not necessary to have used it, for the obstruction was practically removed by chemical absorption previously; yet it was not until I began introducing the large electrode that the woman, to her great satisfaction, found that she could swallow solids and fluids with as much ease and confidence as she ever could. She was consequently discharged as cured on May the 5th. Since then I have examined her on several stated occasions, and have failed to find the slightest recontraction; so I look upon the case as absolutely cured.

CASE III was that of a gentleman—Mr. M.—a resident of Detroit; a liquor-dealer by occupation, fifty-two years of age, temperate in his habits, and of good family history. He consulted me for the first time on May 29, 1889, for difficulty of swallowing. He had suffered from increasing dysphagia for three years, taking sometimes as long as two hours to eat an ordinary meal; but it was not until a few weeks previously to seeing me that he was unable to swallow solid food. The dysphagia developed very gradually from the first, though the man never could assign any cause for it, unless it were from swallowing hot drinks; for he had been in the habit of drinking very hot fluids all his life. His appearance at this time was that of a healthy man, possessing an immense amount of will-power. Though not able to partake of solids, his body was well nourished by milk, beef-tea, beef-broths, and thin arrow-root, which he swallowed in large quantities slowly; yet he was extremely anxious to obtain relief, whatsoever the cost or means employed.

After obtaining the foregoing history I carefully examined the gullet with a No. 6 esophageal bougie. After many trying difficulties I succeeded in passing it through the stricture, which I found was located at the lower portion of the upper third of the esophagus. It was about an inch in length and apparently composed of smooth, dense, fibrous tissue. Galvanism was administered in a mild current—ten milliampères—on May 30th. A negative electrode was by gentle pressure made to pass the obstruction in twenty minutes. This was repeated on the 1st, 2d, 4th, 6th, 8th, and 10th of June, when it was dispensed with for a No. 20 negative electrode; but, owing to the density of the tissues (which were very unyielding), it was with difficulty made to pass the obstruction, requiring an application of thirty minutes' duration, of a current strength of twenty-five milliampères. The electrode was introduced again on the 12th, 15th, 18th, 21st, and 23d of June,

when it passed the fibrous ring without encountering any particular resistance. The man was now able to swallow fluids much more easily, and to partake, too, of finely-minced meat. On the 25th of June I introduced a much larger electrode, two-thirds of an inch in diameter by one and one-half inches in length, with a current-strength of twenty-five milliampères. The electrode was made to pass the stricture in five minutes, with the application of only slight force. It was again introduced on the 28th and 30th of June, when I applied my largest electrode, one inch in diameter by two inches in length, with the same current-strength. On July 1st the electrode passed the obstruction very readily, without causing any pain or inconvenience whatever. This last electrode was again applied on the 3d, 6th, 10th, 16th, 20th, 24th, and August 4th and 10th, when the patient was discharged as cured. He was able to swallow both solids and liquids without experiencing any sense of choking. Since then I have examined his gullet twice and found no recurrence of the stricture. So far he is a perfectly healthy man.

CASE IV is that of Mr. G., forty-seven years old; of German extraction, with a good family history, a printer by trade, and a resident of Detroit. He consulted me August 5, 1890, for difficulty in swallowing, which he declared was occasioned by a long-standing pharyngeal catarrh. Though not intemperate, he drank beer regularly and smoked black plug-tobacco to excess. He frequently suffered with faintness, nausea, and vomiting. Though it was but a year previously to his consulting me that he began to realize that his gullet was gradually narrowing, when I first saw him he was utterly unable to swallow solid food, subsisting wholly for several weeks on nutrient fluids. After obtaining this history I found, on examination, that opposite the cricoid cartilage, just at the beginning of the esophagus, where usually the slightest contraction interferes with the peristaltic action of its circular fibers, there was a general contraction of the gullet, arising principally from a local hypertrophy of the mucous membrance, which yielded readily to a No. 20 esophageal bougie. Simple dilatation was practised for several weeks daily, first with fair results, but I found this too tedious and irritating to the parts, and I again resolved to try electrolysis. The negative electrode, three-quarters inch in diameter by one and one-half inches in length, was applied without difficulty to the thickened portion of the gullet for twenty minutes, with a current-strength of twenty-five milliampères on August 28th, also on the 29th and on Septemper 1st, 8th, and 12th, with splendid results, for the man was at this time able to swallow solids with comparative case. On the 20th I introduced the larger electrode, viz: one inch in diameter by two inches in length, with a current-strength of twenty-five milliampères for twenty minutes. This was repeated again on the 27th, and on October 1st, 10th, 15th, 23d, and 29th, when he was discharged as cured, for he could swallow solids with perfect satisfaction and ease. He still comes to my office every three months to have his gullet electrolyzed, but I have thus far found no evidence of recontraction.

CASE V is that of Mrs. M., of this city, twenty-eight years old, who some ten years ago suffered from esophagitis, which resulted in a general chronic hypertrophic condition, followed ultimately by a diminution in the lumen of the gullet, so that she was unable, especially during the catamenial periods, or when suffering from colds, to swallow solid food. Indeed, during her best spells, she was compelled to masticate her food thoroughly fine, and to have it well moistened with saliva or other fluids, before she dared attempt to swallow it, and then in only small quantities at a time. Her capability of swallowing was, however, gradually lessening, and this thoroughly aroused her to a sense of her true condition, when she was induced to consult me. After learning the true status of her case I made a careful examination of the esophagus, using a No. 15 bougie, and found that the caliber of the gullet was greatly reduced by a general thickening of the mucous membrane interfering with its functional activity. The woman was placed upon electric treatment May 2, 1890. A negative electrode, one-half inch in diameter by one inch in length, was gradually introduced into the diseased gullet, until the cardiac orifice was reached, a current-strength of thirty milliampères being employed for thirty minutes. The application was repeated on the 4th, 6th, 8th, 10th, and 12th, when a five-eighths of an inch electrode was applied on the 14th, 16th, 20th, and 24th, with the same strength of current and for the same time. After the introduction of the last electrode the woman had improved remarkably, for she could swallow solids of every description with perfect ease, without pain or sense of choking, to her great enjoyment. On May 28th and June 4th, 8th, 12th, 15th, and 20th I used the larger electrode, as in other cases, though it was not necessary, and the patient was dismissed as cured. I have examined her esophagus on several occasions since—the last time a month ago—and find that the hypertrophied condition is entirely removed, with no evidence of its recurrence.

CASE VI is that of an elderly lady, fifty-eight years old, a resident of South Dakota, with good family history. She consulted me on the 15th of April, 1891, for a difficulty of swallowing. She stated that she had enjoyed good health until six months previously to consulting me, and that the dysphagia had gradually but rapidly increased until she was unable to swallow even fluids. During the commencement of the trouble she experienced great pain in swallowing, accompanied by a burning sensation in her stomach, which caused her to drool large quantities of tenacious secretion. These symptoms, however, passed away just as gradually as the disease developed, until the gullet became practically occluded, about four weeks previously to her visiting me. Though she had to depend entirely upon nutrient enemata for subsistence during this time, she did not appear to have lost much flesh or courage. Indeed, the only sign of any physical impairment noticeable was a feeling of general weakness, which became quite apparent after gentle exercise. After obtaining this history I made a careful examination of her gullet, and found, as I anticipated, a

formidable obstruction at the cardiac extremity, by which, after many attempts, I failed to pass as small a bougie as No. 4. Being fearful of the dangers that attend forcible dilatation, viz., that of rupturing the diseased part of the gullet, and in view of the fact that the diagnosis was obscure, and the actual result of the case could not be determined, I proposed what I considered then the most reliable surgical procedure, viz., gastrotomy. After due deliberation, this was refused. As time was exceedingly precious, and being fully warned of the probable outcome of her case from delay, the woman, though greatly opposed to the direct administration of galvanism, consented to try it. I must confess that I did not expect good results from it myself, for the canal appeared to me to be entirely obliterated by organic deposits. However, on the 18th of April I introduced a No. 4 negative electrode down to the stricture and applied, with a steady gentle pressure, a mild current, of ten milliampères, which was gradually increased after several minutes to fifteen. The application was suspended for a couple of days, as the patient complained of some pain, with nausea and faintness. The application was repeated on the 20th, 21st, and 22d, with similar results. On the 24th, however, when she found that no bad effects resulted, she was able to withstand a much stronger current; twenty-five milliampères for twenty minutes, without any annoying symptoms whatever. This was repeated on the 25th with the same current-strength, when, to my great astonishment, I discovered, after twenty-five minutes' steady application under gentle pressure, that the electrode passed by the obstruction and entered the stomach. This electrode was again applied on the 26th, 27th, and 28th, with better results. On the 29th I introduced a No. 6 electrode under similar conditions. It passed the obstruction readily, and was used, in all, four consecutive times. On June 5th I introduced a No. 12 electrode, to which the stricture yielded after a few minutes' constant application. This was followed by a No. 20, which was applied on the 6th, 7th, 8th, 9th, and 10th with good results, for the woman at this time was able to swallow warm, nourishing drinks in very small quantities. On June 12th, 13th, 15th, 17th, and 20th I applied an electrode, one-half inch by one inch in length, with the greatest ease. Indeed, the constriction—about an inch in length—appeared to have lost its contractility entirely, as if the obstruction was completely removed, for I was able to pass my largest electrode, one inch in diameter by two inches in length, through the whole of the gullet into the stomach without encountering any particular resistance. Although the peristaltic power of the esophagus was greatly impaired from want of proper stimulus, in consequence of non-usage, the patient was able to swallow fluids slowly, and solids, after being finely minced, in small quantities at a time. The power of deglutition was gradually restored after a few months of regular treatment as rapidly as her general health improved. The woman was discharged in August as practically cured, with the functional activity of the esophagus fully restored. I have recently heard from her, and she declares that she can swallow solids with greater ease than when she was discharged, ten months ago.

Case VII is that of Master C., fourteen years old, anemic and delicate-looking. Four months ago he consulted me for a difficulty in swallowing. I learned that a year previously he had suffered from a severe attack of diphtheria, from which he never fully recovered. Although he was able to swallow nutrient fluids with ease, he found it impossible, from a dread of choking, to swallow solids. On examination, made with perfect ease, I discovered, just at the junction of the esophagus with the pharynx, a slight cicatricial contraction—just enough to interfere with the commencement of the peristaltic action of the circular fibers. Electrization was practised, with forcible dilatation, for several weeks, with perfect success. The boy is now able to swallow as well as he could before he was stricken with diphtheria, and has improved greatly in general appearance, having gained in flesh and strength.

Some of the cases here reported are of too recent date to assure ultimate recovery. I am almost persuaded, however, especially after considering the nature of the strictures as being not morbid in character, that they will not recur. As the majority of them have not received any treatment in more than two years, and I have yet failed to notice the slightest evidence of their recurrence, I think we are justified in claiming them to be permanent cures. In Cases III and VI, I was impressed by the doubt at first as to whether malignancy was at the bottom of them or not; for their ages and the history of the rapid development of the obstruction suggested such a view, though subsequently the strictures proved to belong to the cicatricial variety and to be quite local.

In organic strictures of whatever kind I have, however, never been able to afford more than partial and temporary relief; they are, practically speaking, incurable; for I have not managed to find, after making an extended search through medical literature, that they could be cured.

In thus briefly recording the excellent results derived from electrolytic action in these cases, though they happened to originate primarily from simple inflammatory action, resulting in cicatricial and other deposits of inflammatory products of a non-malignant character, we are compelled to admit, that for safeness, rapidity, and reliability in combating such difficulties, electrolysis has no superior.

It may be true that in Cases IV and VI we could have practised simple dilatation with safe advantage, with perhaps similar results after a longer period of treatment. We can, however, never be certain that dilatation will afford permanent or temporary relief. Again, I have found from personal experience, in several cases, especially if the strictures were in any way unyielding and spasmodic, that the bougies, however gently used, not only caused irritation

and pain, but also aggravated the narrowing. Forcible dilatation or rupture, though it has occasionally been performed with fair results when it was desirable to open up the passageway as quickly as possible, I do not consider a safe proceeding, for the reason that just where the fibrous band or cicatricial contraction springs from the esophageal wall, atrophy of the muscular tissues usually takes place, especially if the stricture is of long standing—a result, no doubt both of defective nutrition and of want of proper peristaltic exercise, so that that portion of the strictured gullet is weak and unprotected from forcible expansion. Indeed, internal esophagotomy is a safer proceeding, if the extent, position, and direction of the incision could be regulated, because less violence is applied to the gullet in the division of a stricture than in forcible rupture. Esophagotomy possesses as well the greater advantage of hastening the process of dilatation. Though internal esophagotomy is ideally the best operative procedure, it is not by any means free from danger, because it is almost impossible to regulate the amount and extent of the division. Of eleven cases operated on for cicatricial stricture, reported by Sir Morell Mackenzie in his admirable book, 28 per cent. died directly from the operation. As Mackenzie curtly remarks, the "thinness of the esophageal walls, the close proximity of many vital organs, and the fact that in disease the gullet is often immediately adherent to surrounding parts, constitute dangers which cannot be ignored," even by the skilled esophagotomist.

In electrolysis, however, we have not only a safe electrochemic weapon, but a reliable one, which has in these cases guaranteed absolute satisfaction. Indeed, I am not acquainted with any other system of treatment that can compare with it in the removal of cicatricial contractions of the gullet. For the sake of argument, it may be said, that since the electrodes were graded and used precisely like dilating esophageal bougies, the process was similar to that of dilatation. I have, however, already shown in several instances, that even simple dilatation is sometimes very irritating, unreliable, and tedious, whereas in these cases the electrochemic bougie was not. It accomplished its purposes in accordance with a just estimate of its utility in some instances, as in Case VI, even after the stricture was acknowledged to be extremely difficult and intractable of treatment.

The Prevention of Tuberculosis in the Dog.—At a meeting of the Académie des Sciences, Richet and Héricourt (*La Médecine Moderne*, No. 24, 1892, p. 387) reported the protection of dogs from human tuberculosis by previous inoculation with the tuberculosis of birds. Of nine animals so treated all survived, while twenty-one control-animals died.

THE TREATMENT OF POSTERIOR ROTATION OF THE OCCIPUT DURING LABOR.[1]

BY EDWARD P. DAVIS, A.M., M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE PHILADELPHIA POLYCLINIC; CLINICAL LECTURER ON OBSTETRICS IN JEFFERSON MEDICAL COLLEGE; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

AMONG the complications of labor not requiring surgical interference none is more important or fraught with greater danger to child and mother than posterior rotation of the occiput. We desire to substitute this term for that commonly employed —"occipito-posterior positions"—believing that the method of obstetric study that recognizes but two positions for each presentation is more rational and serves a better purpose than the more complicated system that calls for many positions. We shall then make but two positions for each presentation; for example, a vertex presentation has a first and a second position. The first is the usual one, the back of the child directed toward the left side of the mother and the vertex directed slightly toward the left side of the mother's pelvis. The second position of a vertex presentation is that in which the back of the child is directed toward the mother's right side and the occiput points to the right of the mother's pelvis.

During labor the occiput, in the vast majority of cases, turns forward, toward the symphysis pubis. Occasionally it descends through the pelvis, showing a tendency to turn posteriorly, thus giving rise to what have been styled "posterior positions." It occasionally happens that during pregnancy the occiput is situated behind the center of the mother's pelvis; whether the occiput endeavors to turn backward, or whether during pregnancy it is situated slightly behind the center of the pelvis, it is more rational and easier of comprehension to call this abnormal turning of the occiput "posterior rotation" than to make four positions, two of them posterior. In common with many Continental students of obstetrics, we style the condition as an "abnormal rotation of the occiput," and not as "occipito-posterior positions."

The causes of the tendency to turn posteriorly are several. The mother's pelvis may be narrowed in its anterior half and its sides may lack those surfaces anteriorly to a line drawn upward and forward from the spines of the ischia that normally favor the anterior turning of the head. The head of the child may be of unusual size or contour, finding its most convenient lodgment at the posterior extremity of one of the oblique diameters of the pelvic brim. Again, during labor, the posture assumed by the mother may not be such as to favor the anterior

[1] Read at the meeting of the American Medical Association, Detroit, June, 1892.

turning of the vertex. Many cases exist in which no one factor has been found to be entirely responsible for the abnormality; thus, a small child may enter the pelvis with its head in partial extension or flexion, and this intermediate condition remaining, the occiput may turn toward the hollow of the sacrum.

Some of the symptoms of posterior rotation of the occiput may be perceived before labor has actually begun, while others are discernible only after the commencement of labor. Palpation and auscultation will often reveal the fact that the occiput is directed toward the middle line or even slightly behind the center of the pelvic brim. The back of the child may be turned somewhat posteriorly, so that the heart-sounds seem to come from deep in one side of the mother's abdomen. If the abdominal walls are thin the occiput can be mapped out and accurately located. If a history of previous labors be sought there will be an account of prolonged parturition, probably ended by instrumental delivery, and often resulting in the death of the fetus.

At the time of labor it is often difficult to map out accurately the position of the head unless the tissues be elastic and admit of manipulation. If the attending physician notices the absence of the vertex in the anterior half of the mother's pelvis he will do well to allow her to inhale sufficient chloroform to permit the introduction into the vagina of enough of the hand to make a positive diagnosis.

We shall best understand the indications for treatment by considering briefly the course of a hypothetic case if left to nature. Statistics show that the greater number of cases result in anterior rotation of the occiput without assistance. By some the proportion of cases that rotate spontaneously to the front is placed as high as 96 per cent.; others allow but 75 per cent. My own observation and the records of 219 cases occurring at the Philadelphia Hospital lead me to believe that 87 per cent. of these cases terminate spontaneously with anterior rotation. A source of fallacy in a study of the question arises from the fact that an exact diagnosis of the position of the head is rarely made early in labor; a practitioner is often satisfied with finding that the head is presenting and that the face is not the part found by the examining finger. Thus, a case in which posterior rotation has begun, but which terminates by turning forward, is not recognized until anterior rotation has occurred.

If we seek to ascertain the factors upon which anterior rotation depends, we find them to be essentially three in number: First, a normal proportion in size between the head and the pelvis; thus, a small head in a small pelvis favors normal rotation, and a large head in a large pelvis is likewise favorable. Secondly, a flexed position of the head is essential to anterior rotation of the occiput. Thirdly, the forces of labor must be normal, namely, the contractions of the uterus and the resistance afforded by the pelvic floor. If any one of these factors is notably deficient, a perversion of rotation is very likely to occur.

Abnormal rotation of the occiput is a source of danger to the life of the child and to the integrity of the mother's tissues and also to her life. The child's life is jeopardized by long-continued pressure during prolonged labor, resulting in visceral hemorrhage and death. The mother's tissues are endangered by reason of the abnormal prolongation of the pressure of the head during efforts at rotation, while her life is imperilled by the added risk of septic infection and exhaustion.

The treatment of such abnormal rotation would rationally consist in an effort to supply the one or more factors already described that may be deficient or perverted. Although the physician cannot remedy disproportion in size between the head and the pelvis, the sooner he becomes aware of such disproportion the better for his patient. No woman should be attended during her first pregnancy unless her pelvis has been measured by her medical attendant. In making this statement we do not insist upon an elaborate measurement of the pelvis, but urge that three external measurements be invariably made. These are: the external conjugate, the distance between the anterior superior iliac spines, and the distance between the outermost points of the iliac crests. If the physician has the opportunity of making such an examination as early as the thirtieth week of gestation, he may, if necessary, be able to induce labor, thus securing a normal rotation of the occiput before disproportion between the head and the pelvis has gone so far as to endanger his patient. If he does not see his patient until she is considerably advanced in labor, the knowledge that her pelvis is smaller than the average will be of great value in preventing the futile effort to deliver a large head through a pelvis too small for it. In addition to the measurement of the mother's pelvis, an effort should be made to ascertain the comparative sizes of the head and the pelvis. This can be done by placing the patient upon her back, her thighs being flexed, while the fetal head is gently pressed downward into the pelvis by the examining hand laid broadly behind the pubes, the other hand steadying the fundus of the uterus. If more exact information is desired, one hand may be placed against the head by internal examination, while pressure is exerted with the other hand behind the pubes. A head that begins to slip into the brim of the pelvis under such manipulation is not too large to rotate successfully during labor.

Flexion of the head, necessary to secure anterior rotation, may be promoted and maintained by the employment of the hand, accompanied by the use of forceps. When the physician discovers that the occiput is turning posteriorly, while the head is but slightly flexed, if the patient be anesthetized sufficiently to permit the introduction of the hand, the occiput may then be drawn down, or the chin pushed upward, and flexion secured. If this effort fails, flexion may be secured by axis-traction with the forceps, as will be described in a succeeding paragraph.

Flexion and anterior rotation may be further facilitated by the posture of the patient; thus, if the back of the child be turned toward the left side of the mother and the occiput tends to rotate posteriorly, the mother should be turned upon her left side, with her thighs flexed and her shoulders bent slightly forward. This posture causes the fundus of the uterus, containing the body of the fetus, to fall toward the left side of the mother's spinal column, as it will be remembered that the uterus normally occupies a position of right lateral obliquity in the abdomen of the mother. This movement of the fundus from right to left, by gravitation, favors the turning of the occiput from left to right, and thus anterior rotation of the vertex is expedited. If the child's back is directed toward the right side of the mother and the occiput seems about turning toward the sacrum, the mother should be placed upon her right side, with her body flexed as has been described and her right side propped up from the bed by means of pillows. Gravitation of the fundus is thus favored, and anterior rotation is more likely to occur.

The posture often instinctively assumed by women, namely, that of kneeling strongly forward upon the bed, is one that favors flexion and anterior rotation. The fundus of the uterus falls forward, the head tends to flex and descend into the pelvic cavity, and the long axis of the fetus corresponds more perfectly with the direction of the axis of the pelvis.

In addition to posture, constant external pressure against the vertex sometimes favors anterior rotation of the occiput. Thus, I remember having seen a case so treated in the wards of a foreign hospital; the patient was placed upon her side and a small bag filled with sand was laid upon the abdomen against the vertex.

We now come to consider the last of the three conditions upon which anterior rotation depends, namely, the expulsive force of the uterus and abdominal muscles, and the resistance of the pelvic floor. If the former is deficient, a suitable stimulant to the nervous system is indicated; thus tea, coffee, alcohol and quinine are most available; it is rarely necessary to employ ergot, and exceptionally the faradic current of electricity has been found useful. A narcotic that causes labor to cease absolutely for a time, while the patient sleeps, has often been found of value, the patient on awakening rousing to renewed activity. Direct stimulation of the uterus by rubbing the abdomen, and by pressure exerted upon the head in the axis of the pelvis, may carry to a successful parturition a labor lingering in its last stage. Again, anesthesia of a moderate degree may temporarily remove the depressing influence of pain and cause renewed uterine activity.

While such expedients are frequently successful, yet the forceps is very often the last resource of the practitioner. In this, as in all forceps deliveries, two methods are to be distinguished. One is that which all that use forceps desire to carry out, namely, the application of the blades accurately to the sides of the child's head; this requires a forceps modelled after French instruments, or shaped like the familiar blade devised by Davis, of London.

The other method of applying the forceps is that recognized as a valuable expedient, although not the ideal method of operating; this is the application of the forceps to the sides of the pelvis, and suggests the employment of an instrument modelled after the forceps of Simpson, of Edinburgh. In the first instance, forceps and head rotate together; in the second, the head rotates in the forceps, the blades remaining in the axis of the pelvis at the sides of its cavity. The first method requires for its safe performance a very accurate diagnosis of the precise location of the occiput; this will usually require anesthetizing the patient and the introduction of nearly all or of the entire hand within the vagina. In the second method the occiput may not be definitely located, although its absence from its usual location may have been determined. The forceps is then applied to the sides of the pelvis, traction is made gently with the pains, and between the tractions the grasp of the forceps is relaxed, the head rotating within the forceps-blades, so that each application is virtually a new one.

Neither use of the forceps is skilful that does not at the same time employ axis-traction. All obstetricians are familiar with the simple manipulation of performing axis-traction with the hands, grasping the handles of the forceps with one hand and raising them, while the other presses downward and backward upon the instrument at the shank. If the case be a difficult one, this requires for its successful performance very considerable strength in the hands and wrists. The axis-traction forceps of Tarnier and those modelled after it represent an established method of securing axis-traction in these cases. The Tarnier instrument, however, is not convenient for the ordinary exigencies of confinement; it is too heavy, too large, and too expen-

sive. Poullet, of Lyons, in a thesis described the application of the tapes as tractors to secure axis-traction. Many had already employed this, or a similar device, by passing a tape or cord around the shank of the forceps, and forming a loop into which the foot of the operator could rest, and by downward traction assist in the delivery. Poullet has modified and made more simple his use of the tapes, as shown in his most recent instruments. I applied the tapes, as first suggested by Poullet, to the Simpson forceps for the purpose of meeting the indications in those cases in which the occiput tends to rotate posteriorly, and in which the Simpson forceps applied to the sides of the pelvis seems most clearly indicated. The tapes have been similarly attached to the Davis forceps for cases in which that instrument seems most suitable; my experience leads me to prefer the Tarnier forceps in cases in which the instrument can be applied accurately to the sides of the head.

In using the forceps with the tapes no extra device for holding the instrument tightly upon the head is necessary. As traction is made, the tapes tend to draw the blades together; thus, in using the Simpson forceps, care should be exercised that the blades do not approach too closely.

In using either form of instrument, but moderate force is needed to effect delivery, provided axis-traction be made; the failure to perform axis-traction accounts for many of the difficult and dangerous cases of forceps-delivery. The head should be kept thoroughly flexed during its exit from the genital tract; the use of axis-traction has largely done away with that function of the forceps said to favor rotation. No one would attempt to forcibly twist a vertex in the pelvis; the difference between traction in the axis of the pelvis and the attempt to deliver without such traction can never be appreciated without a practical experience with the two methods. The former is a difficult, tedious, and laborious task; the latter is a matter of much less difficulty. As illustrating the method of favoring rotation by axis-traction with the Simpson forceps, the following case, reported originally in the first volume of the *Philadelphia Hospital Reports*, may be described:[1]

M. H., thirty-six years, an Irish domestic, unmarried, a unipara, was admitted to the hospital October 16, 1889, in a fairly good condition. While awaiting delivery she suffered from numerous severe attacks of asthma, and was found to have emphysema, with some dilatation of the right ventricle. Examination of the heart revealed no valvular lesion, and examination of the urine showed an absence of albumin and of casts. For the relief of the asthma, grindelia robusta, potassium nitrite, and soda, with chloroform-inhalations, were employed. During the woman's stay in the obstetric ward her general condition did not improve, the attacks of asthma increasing in frequency, the patient becoming anemic, irritable, and weak. About three weeks before labor, albumin in considerable amount was found in the urine, and about a week later the legs and feet became edematous.

Labor began Tuesday, December 24, at 10.30 P.M., the patient reaching the maternity ward at 10.30 P.M., December 25, 1889. At this time she was weak and irritable; she suffered from dyspepsia and complained of pain in the back. The os was patulous to one finger; no presenting part could be felt, polyhydramnios being present; the uterine contractions were infrequent, of slight force, but caused great suffering. The first stage of labor lasted sixty-two hours, the general condition of things remaining much as described; the abdomen was enormously distended, tense, fluctuating; the fetal heart was distinctly heard low down in the right flank. The position of the fetus could not be made out by palpation. The patient became weaker, the pulse losing in volume and increasing in frequency to 115. At an early hour in the morning of December 28th the membranes ruptured, and a large amount of greenish liquor amnii escaped, but the head, which presented in the right occipito-posterior position, prevented the escape of all. It was now found that the woman's bladder was full of urine, and catheterization was necessary. Still the head failed to descend through the pelvis, which was not markedly contracted, the measurements being: Spines, 23.5 cm.; iliac crests, 26.5 cm.; external conjugate, 18 cm.; right diagonal, 22 cm.; left diagonal, 21 cm.; trochanters, 28.5 cm.; circumference, 85 cm.

The contractions of the uterus diminished in force, and at 12.30 P.M., December 28th, the patient was anesthetized with chloroform; Simpson's forceps, with the Poullet tapes attached, was applied, and the head delivered. The cord was wound twice around the neck. Delivery was difficult, consuming considerably over an hour; the occiput remained posterior until just before delivery, when it quickly rotated forward. The grasp of the forceps was relaxed between the tractions to allow rotation. Double episiotomy was practised, and no considerable laceration occurred.

In bringing this paper to a conclusion, I desire first to draw attention to some errors that I think not uncommon in the treatment of these cases. Of primal importance in this report is the neglect of the effort to measure the patient's pelvis when possible, and when this is not practicable to estimate the comparative sizes of the head of the child and the mother's birth-canal. In this the profession must educate its patients, and this can be done only if methods of examination are conducted without exposure, without violence, and in a kindly and skilful manner. It is my custom to teach students to examine the pelvis, diagnosticate the position of the child and its presentation, and ascertain whether

[1] Philadelphia Hospital Reports, vol. i, p. 229.

the head is likely to enter the pelvis readily, while the patient remains covered by one thickness of linen. We can no longer comfort ourselves with the remark that American-born women rarely have contracted pelves; this statement is not strictly true, and the large number of foreigners coming to our country show frequent examples of varying degrees of pelvic malformation. The skilful obstetrician, by his knowledge, avoids prolonged and disastrous labors, and such good results are impossible without a skilful examination of the pregnant patient. If a large head be detected at the brim of the pelvis, scarcely able to enter, and showing a disposition to rotate posteriorly, it will be found better practice in many cases to perform the conservative Cæsarean section, saving the lives of mother and child, rather than subjecting the child's life to great risks and exposing the mother to serious injury in delivery.

I desire, secondly, to draw attention to the efficacy of posture in favoring rotation of the occiput when the head has entered the pelvis. Whether it be that the patient lies upon the side toward which the occiput is pointing, or whether she inclines the pelvis forwards, I am convinced from observation that posture is a valuable adjunct in the conduct of such cases. I desire also to criticise that method of examination consisting in the introduction of but a portion of one or two fingers in the effort to make an accurate diagnosis of the location of the occiput, and to favor its anterior turning. The practitioner should prepare himself to apply the forceps if necessary, and then anesthetize his patient to obstetric anesthesia, preferably with chloroform; he should introduce so much of the hand as may be necessary to make an accurate examination of the entire vertex. In the intervals between the pains he will be able to favor anterior rotation, and when he has thus brought the vertex in front of the middle of the pelvis, without removing the hand the forceps may be applied and the labor terminated.

Third. The forceps is often applied too soon, thus neglecting one important factor in anterior rotation, namely, the resistance of the pelvic floor. If the forceps be applied before the head has had an opportunity to rotate upon the pelvic floor, its posterior turning is often favored by the instrument rather than its anterior rotation. On the other hand, the forceps is often applied too late, when flexion has become impossible by reason of the persistence of partial extension, the head becoming impacted upon the pelvic floor in this unfavorable position. The life of the child has frequently been lost in such cases before the final effort at delivery is made, and when such is the case craniotomy is often the only rational procedure.

In conclusion, I would urge the following as points of importance: First, the adoption of the simple nomenclature already stated, which has borne the test of usage on the Continent of Europe, and which will render more comprehensible the mechanism of labor. I refer to the designation of two positions only for each presentatation, anterior or posterior rotation being designated, as the case may be. Second, the importance of pelvimetry and of the comparative estimation of the sizes of the head and the pelvis is paramount; by the second of these I mean the careful estimation as to the degree of engagement of the head, and if the head has not engaged, pressing it gently into the pelvis by supra-pubic pressure, the patient being, if necessary, partially anesthetized. Third, when the head is proportionate in size to the pelvis, and lingers upon the pelvic floor by reason of failure in expulsive force, the child's life and also the mother's safety being in danger, the forceps should invariably be used with axis-traction. The forceps should be used in accordance with the possibilities of the case, and that form of instrument should be selected that was intended for such possibilities. Whenever practicable, forceps designed to be so applied should be accurately placed upon the sides of the child's head, axis-traction made, the head and the forceps rotating together anteriorly. When such accurate apposition is impossible, forceps modelled for application to the sides of the pelvis should be employed with axis-traction, the forceps making as little pressure as possible upon the head, the blades being relaxed after each traction so that rotation anteriorly may occur between the blades. Fourth, a conservative Cæsarean section may be indicated if a living child, with large, firmly ossified head, presents with a posterior rotation of the occiput, the head failing to descend into the pelvic cavity; craniotomy may be indicated if such a child has perished during its entrance into the pelvis.

THE GENESIS OF CROUPOUS PNEUMONIA.[1]

BY WILLIAM W. PENNELL, M.D.,
OF FREDERICKTOWN, OHIO.

FROM being regarded as the result of a common cold to the more scientific opinion that it is the effect of a vegetable microörganism acting upon the animal economy; from being supposed to be a local inflammation to the view that it is a zymotic or essential fever, with pulmonary lesions, only the general causes of pneumonia are known, the specific being undetermined and a matter of conjecture. Under such conditions it is held the rightful duty of every observer along the line to cast his mite into the general treasury of such knowledge, that the

[1] Read in the Section on Medicine of the American Medical Association, Detroit, Mich., June 9, 1892.

causal agency may ultimately be disclosed, as has occurred in other diseases. The subject-matter of this paper is mainly constituted of personal observation and deduction, and is offered for what it is worth.

Is pneumonia a local disease or an essential fever? The question is rather antiquated and behind the times. As a local inflammation, attended by a symptomatic fever, its causes must be similar to those of any other local inflammation that may have been produced by any thermal, toxic, chemical, dyscrasic, or mechanical influence. Such a process is almost necessarily attended by fever, a resultant of absorption of certain materials from the affected part, whatever the cause, or arising from a nervous disproportion between the production and dissipation of heat. That a pulmonary inflammation should differ from one of some other organ is not clear, unless its course, effects, and morbid anatomy are distinctive and unless only certain causes always produce it to the exclusion of every other. Simple inflammations often follow slight causes when the bodily health has been lowered by some antecedent influence; the cause not abiding, the process soon subsides, the exudate being absorbed and the part assuming its normal state. So a fleeting or an abiding cause regulates the duration of any morbid process.

In local inflammations, the location and surroundings in which exudations occur are the parts upon which the causative agent had been most forcibly exerted, the previous condition of such a part being unknown and not observable. The course of such an inflammation will be influenced more by the condition of the individual than by its cause or causes, such condition determining the sthenic or asthenic form of the inflammatory process. Its duration is governed by the transient or continuous origin, and is classified by the anatomic changes observed in the part inflamed.

Acute inflammations, due to transient causes, usually end in resolution and restoration of function. If the general health have been greatly impaired previously or during the attack, the inflammation may result in suppuration or purulent infiltration.

Yet it is the rule, even in the unhealthy, for the inflammatory process to stop short of abscess. Purulent formations, when they do occur, are generally supposed to be of bacterial origin, as bacteria are believed by many to cause every form and grade of inflammation.

In severe, acute inflammatory states attended by pus-formation, special microörganisms are well known, and are always found to be present. It is true, also, that organisms having no known noxious influence, either by themselves or by their products, are generally abundantly present. It follows that most bacteria are innocuous and incapable of producing inflammation, either by their intrinsic harmlessness or by their inability to carry the citadel of fairly normal tissues. No doubt there are bacteria capable of producing every kind of inflammation, yet incompetent to excite suppuration. To me it has seemed that there must be some agency to weaken the normal resistance of tissues before these organisms can operate successfully, and that bacteria, as a causative agency, are secondary and considerably overestimated. Those usually found asssociated with pneumonia are present in health and are apparently harmless—for aught we know are benign in disease, as the inflammations produced from pure cultures usually differ from the primary.

In croupous pneumonia we have a typical fibrinous inflammation, beginning with congestion and serous exudation, resulting in a filling of the alveoli and infundibula of the lobe affected with inflammatory products, or hepatization, and ending usually in resolution and occasionally in purulent infiltration. So far, the process resembles any other local inflammation. In its course, duration, character, and termination, it is in some respects analogous to specific diseases; in others the analogy is quite lost. That some cases are wholly specific, we believe. Some authorities,[1] however, assume that the disease has every feature of a zymotic disease in the same sense as cholera, typhoid fever, smallpox, etc., and that a house having bad ventilation and sanitation, and having been once infected by pneumoniacocci, becomes their abode, because they find suitable soil for growth and multiplication, and are received into the system probably by inhalation, thereby causing frequent recurrences of the disease among the occupants. If this picture is absolutely accurate, then the same cleansing and fumigation is necessary in most houses after an attack of pneumonia as is needed after every case of smallpox, diphtheria, and allied diseases. The crowded tenement-houses of cities no doubt furnish such instances, but in the country and smaller towns, in the writer's experience, nothing of the kind has been encountered. Indeed, this seems to me an extreme view, because poor ventilation and bad sanitation in their entirety have often been found, while the infectious character of pneumonia has not been observed.

If pneumonia is infectious or contagious, then all that I have seen in over seventeen years has been of the sporadic variety—quite a different experience from that of other infectious maladies. I have seen typhoid fever and diphtheria attack one member of a family after another; I have seen several stricken at the same time; yet nothing of the kind has been observed in regard to pneumonia. Were this view

[1] Keating: Dis. Children, vol. ii, p. 588.

the usual experience of physicians everywhere, the specific character of pneumonia would have demonstrated itself long ago, as is daily demonstrated by zymotic diseases in every clime.

As telling against the zymotic nature of pneumonia, compared with typhoid fever: The former has been observed in the same individual a number of times; the latter but once. Pneumonia leaves the individual prone to subsequent attacks; whereas typhoid fever appears to confer immunity. This tendency to other attacks of pneumonia makes it resemble diphtheria, but, unlike that disease, it is not contagious. Then, no prodromal period has been observed, as in zymotic disorders, the onset being sudden. The course was generally severe and always short and not followed by sequelæ, as in typhoid fever, measles, diphtheria, etc. Pneumonia terminated by crisis, save in cases ending in purulent infiltration or abscess; in these few, if death did not soon take place, recovery was retarded, as in other purulent formations.

I do not remember a case terminating by lysis; and yet a critical ending in zymotic disease has been the exception—indicating the gradual elimination of the poison, or rather, perhaps, the return of the bodily resistance to bacterial infection. Inasmuch as we are taught that pneumonia is wholly a specific fever, I have often asked myself, What is it that destroys the poison so quickly and so thoroughly? Is this poison deposited in the exudate, and thereby rendered innocuous—a quarantine established by Nature for her own protection? I cannot fathom it.

To myself, not looking at the question from a bacterial standpoint, it has appeared that crisis occurs in two ways: 1. In all favorable cases, in from three to seven days, there is sufficient discharge or drainage to secure resolution, just as I have seen slight wounds that some good-souled mother had hermetically sealed by adhesive plaster that prevented a small amount of pus escaping, followed by chill, fever, and delirium, that terminated as soon as the plaster was removed and drainage was established. 2. The cause that excited the inflammation exerted its influence for but a short time, the resulting disturbance being the effects of an agent that acted traumatically and then withdrew, leaving a simple exudation.

The fact that the encapsulated coccus of Fraenkel has been found in the tissue of pneumonic lungs in 92 per cent. of cases examined is certainly inconclusive, because that germ is always present in the saliva of healthy individuals, and, for aught we know, in the lungs also; beside, their absence in even less than 8 per cent. renders the argument worthless. The character played by the pneumonia-coccus of Friedländer as an exciting cause of those pneumonias terminating in suppuration is unknown, but certainly the conditions favorable to the formation of pus are abundant, just as they are in pleuritis, hepatitis, and nephritis.

Another objection to the conception of the specific nature of pneumonia is that the disease is frequently aborted by antiphlogistic treatment, a rather infrequent result in zymotic diseases. I do not remember having seen a case of specific illness aborted, but I have seen cases prevented. At a meeting of the Philadelphia County Medical Society, April 13, 1892,[1] Dr. Hiram Corson read a paper on "Pneumonia and Its Treatment," in which he advocated venesection as a controlling remedy of the highest order, and states this to be the result of "over sixty-five years of careful, anxious observation." The results of his long experience are worthy of consideration, even if we no longer bleed.

On every hand appear the opinions of different observers as to the specific or non-specific nature of pneumonia. It appears that the idea of the zymotic origin of pneumonitis is widely diffused and gaining ground, and they that cannot see the way so clearly are in the background and perhaps moss-grown, not having given bacteriology as full study as it deserves. These fossils, however, admit the specific origin of known zymotic diseases.

In my own experience the immediate causes of pneumonia are few. Common cold is not one of them, for were this a cause pneumonitis would be wondrously prevalent when colds are abundant. On the other hand, continued exposure and exertion during seasons of the year having great thermometric range and conditions connected therewith would, in certain individuals, excite pneumonia; while others similarly exposed would escape.

I have seen the "dust chill" experienced by farmers after threshing in the heat followed by as typical a pneumonia as that consequent upon a prolonged drunken spree, while others similarly engaged entirely escaped. I have seen pneumonia as fully developed secondarily to chronic cystitis, arthritis, uremia, measles, etc., as it has been seen following vicious or licentious habits, yet many persons similarly exposed remained exempt. I have seen pneumonia as complete following the accidental inspiration of a portion of hazel-shell into the right bronchus, where it remained a few hours, being expelled by violent coughing; while contrarily, a child had a coiled piece of tin in the same situation for twenty-six days, without such effect. I have seen pneumonia follow the inhalation of dust by sawyers, the small particles being probably aspirated into smaller tubes and alveoli, a crisis being favored by expectoration. I have seen pneumonia follow unusual exposure to cold and wet in conditions of

[1] Journal Am. Med. Assoc., May 14, 1892.

hunger, debility, or intoxication, while some persons could withstand similar exposure with impunity, so far as pneumonia was concerned.

Sex makes no difference under similar depressing influences, and persons of an age anywhere from six months to forty years, especially in infancy and youth, are most liable to the disease. Pneumonia has been observed in early life, before a vigorous constitution is developed and when tendencies are uppermost; or in adult age, when the circumstances surrounding an active stage or when depressing agencies brought to the surface the latent tendencies of the individual. The degenerations and waning powers of old age have been nearly the same in effect as infancy or youth.

I have seen pneumonia in the wake of bad hygiene, poor sanitation, enervating habits, and overwork, and yet conditions the reverse of these were found inadequate to prevent it if some physical debility existed. To me it appears that some individuals and certain families are more disposed to this form of inflammation of the lungs than others, and that three factors alone are necessary to produce a pneumonia: 1. A predisposition or tendency. 2. Loss or lack of normal tissue-resistance. 3. An exciting cause. The result would be a pneumonic inflammation, alteration of the blood, fever and nervous phenomena.

1. Tendency may depend upon a previous pneumonia, dyscrasia, or family history of pulmonary weakness, favored by depressing, weakening habits and pursuits, age and surroundings.

2. While all the associated predisposing conditions and influences act on all alike, not all succumb to the development of pneumonia, because not in possession of essential predisposition.

3. The first two requisites being present, any exciting cause, be it dust, season, poisonous materials in the blood, microörganisms, or the manifold and diverse circumstances that tend to inflammation, would develop a pneumonia, its degree, course, and termination being influenced by the exciting cause: an inflammation not purely local nor yet bacterial or specific, but due to a systemic condition that permits many and diverse agencies to excite, rather than some other form of disease. It follows that a patient should be made and kept as aseptic as possible until the crisis is thoroughly established.

CLINICAL MEMORANDA.

A NEW OPERATION FOR LACERATED PERINEUM.

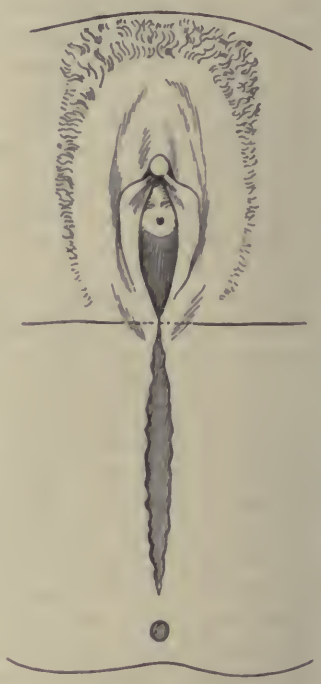
BY JOSEPH A. MULLEN,
UNDERGRADUATE OF JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THE operation herewith proposed for the restoration of a lacerated perineum is as follows. For convenience of description I have divided it into different stages, and for sake of brevity of illustration I have taken a median tear:

1. The first step is to freshen up with scissors or scalpel the inner and lateral surfaces of the laceration, the same as would be done in Hegar's operation, or the simple median operation.

2. After this has been performed, temporarily suture together the two anterior extremities of the lacerated perineum, so as to gain a solid stay for further steps in the operation.

I



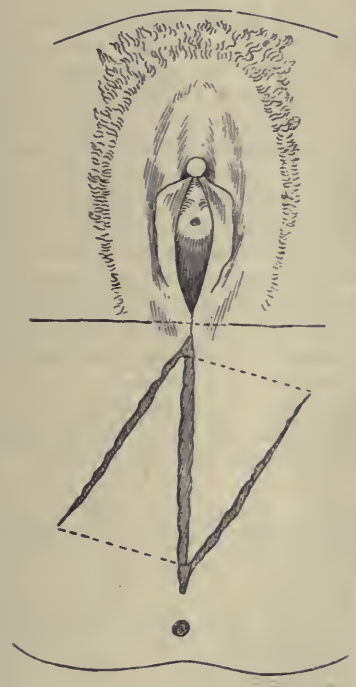
3. The first incision will be triangular in shape, and can be made on either side, commencing, in this case, on the right side, from one-eighth to one-half of an inch from the anterior margin of perineum, the apex being toward the latter and the base toward the interval between the anus and the ischial tuberosity. Begin the apex on the right lateral perineal margin, as already stated, making the incision as deep as necessary, and extending it to an angle of from twenty to forty degrees, and continuing it until a line drawn transversely from its basal extremity to the laceration would meet the latter from one-eighth to one-half of an inch from the anal extremity of tear. This distance will, of course, vary greatly, the variations depending on the amount of tissue present.

4. The second flap will be the reverse of the preceding one, *i. e.*, the apex will point in the direction of the rectal extremity of the laceration, beginning from one-eighth to one-half of an inch from the anal extremity of the tear, cutting upward and outward, so that the base of the flap will be continuous with a transverse line drawn from its extremity to a point from one-eighth to one-half of an inch from the anterior perineal margin in the median line. The depth of these incisions will

depend upon the tissue present and the size of the perineum.

5. After these two triangular flaps have been made, both being of equal dimensions and of whatever depth is desired, dissect the under surface free from the underlying tissue. When this has been thoroughly done, lift up with forceps the apex of the left triangular flap with

II



one hand, and with the other grasp the apex of the right flap, depressing it and at the same time gently pulling the left flap to the right side of the perineum and the right flap to the left perineal side, fitting them accurately in position. The apex of the right triangle snugly fits on the inner or ischial aspect of the base of the left flap, looking toward the fourchette; the apex of the left triangle will adapt itself to the base of the right flap, toward its ischial or inner side.

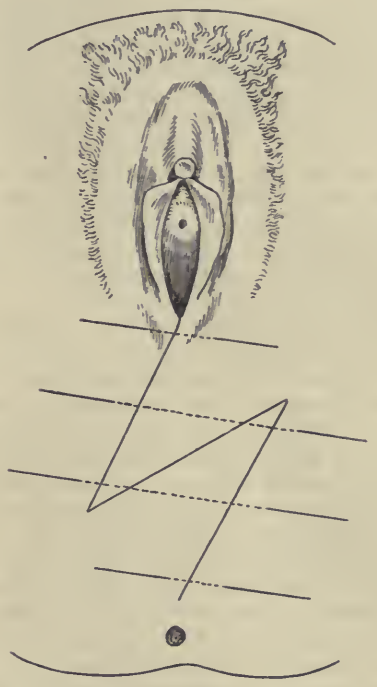
When the two flaps have been carefully adjusted, all that now remains is to suture the parts together. To get the flaps of the proper size requires no especial skill whatever, only the necessary care and attention requisite for any perineal operation. The dissections of the flaps are no more difficult than those in Tait's or in Martin's operation.

I believe it much better to commence suturing from the posterior extremity of the laceration, passing the needle, armed with the necessary suturing material, from the left to the right side through that portion of the perineum external to the base of the right flap, and so on to the anterior perineal margin.

The advantages of this operation are several: No tissue is wasted excepting that removed in freshening the lacerated margins (if they be old), and with this economy of tissue there is no corrugation or puckering of the perineum, which, among other disadvantages, is very likely to render the perineum smaller, thereby increasing the tendency to subsequent rupture. The saving of tissue, as in operation on any portion of the body, is of the utmost importance in enhancing the usefulness of the parts.

By the foregoing method the strength of the perineum is greatly increased. This will become evident when

III



the position and shape of the flaps are considered. The anterior extremity of laceration will have been pulled to one or the other side, bringing intact tissue into the median line, and there will also be a bar of cicatrical tissue running obliquely across the perineum. If properly performed, the operation will leave the perineum fortified by cicatricial bands of support. But, after all, the most essential element in all operations on the perineum is to retain as much tissue as possible, and also to preserve the integrity, shape, and size of the perineum, and to leave it as near as possible in the condition in which it was before laceration.

A CASE OF TUBERCULOUS ADENITIS WITH GENERAL ALOPECIA AND PRURITUS.[1]

BY JAMES H. DUNN, M.D.,
OF MINNEAPOLIS, MINN.

THE case of tuberculosis of the lymph-nodes herewith reported, presents some phases in its clinical history that were to me quite novel, particularly the general alopecia and pruritus, which during the first year of the disease were the patient's chief plague.

Early in April, 1890, D. McA., an Irish-American

[1] Read in the Section of Dermatology and Syphilography of the American Medical Association, at Detroit, June 7, 8, and 9, 1892.

farmer, twenty-one years old, came under my observation. His father, mother, and several brothers and sisters were all living and healthy. Of more distant relatives he knew but little, but he denied any rumor or knowledge of a tuberculous family record. He has been a healthy and athletic young man, five feet nine inches in height, with a weight of 185 pounds. His hair and complexion were light; his eyes bright and blue. For several years he had each autumn been engaged in "feeding" a threshing machine. While employed in this very dusty work during the fall of 1888 he began to cough, without expectoration; he noticed marked enlargement of his cervical glands, and began to be annoyed by a terrible itching of the surface of his whole body. These troubles were attributed to his dusty employment, but after his fall work was over, the cough and pruritus not abating, he consulted a physician, was better for a time, and able to work until the fall of 1889, when, while again threshing, he became much worse, the pruritus especially being so intense that he came to the city and consulted a dermatologist—my esteemed friend, Dr. Vanderhorck.

In April, 1890, his parents sent him to St. Mary's Hospital, where he fell into my hands. At this time the lymphatic glands of the cervical and axillary regions were much enlarged, varying in size from a hazelnut to a hen's egg. None of these glands had suppurated, nor did they in the further course of the disease show any of the usual tendency of tuberculous glands to break down. On the right side of the neck, the mass of tumors was so great as to constitute a noticeable deformity. Respiration was very labored, and an almost incessant dry, barking cough plagued the patient night and day. He was incessantly rubbing and scratching. The skin was remarkably anemic, somewhat thickened, and slightly pigmented from long scratching. There was no eruption, excepting the scratch-marks, which were most numerous upon the legs, next so on the thighs and forearms, then on the arms. The whole surface itched, and, while conversing, the man was always engaged in rubbing the face, the scalp, or some other part. His body was almost devoid of hairs, which had fallen out since this itching began. There was a very scanty and scattered growth upon parts of the scalp, but absolutely none elsewhere; eyebrows, eyelashes, pubic hairs, etc., were wanting. His appetite was poor, and he was much reduced from loss of sleep.

On examination of the chest by several physicians there was found to be extensive dulness over the mediastinum, both in front and behind, and extending some distance to the right and left of the sternum, which all agreed was due to an extensive growth or mass of greatly enlarged tracheo-bronchial glands. The spleen was not perceptibly enlarged. After considerable study and observation of the case, I concluded that it was one of Hodgkin's disease, the pruritus and alopecia being due to pressure-disturbances of the sympathetic system.

As I was unable to relieve any of his symptoms I sent him to my colleague, Dr. J. W. Bell, who put him upon cod-liver oil and arsenic, I believe, remedies that we had tried in vain, and in less than a week he became, as he said, almost a well man. The enlarged glands diminished in size; the cough nearly ceased; the pruritus abated; he slept and ate. Of course, the glandular enlargement and all the attendant symptoms had several times in the course of the disease receded and advanced, but never, since the disease had been so bad, had the change been so marked. He left the hospital July 11th in great hopes, though his family was informed that the respite was only temporary.

This lull in the fury of the disease lasted about one month, until August; then the old symptoms all returned. I saw him no more until at the post-mortem examination, but learned from his father and attendants that during the period of betterment his hair grew quite thick and he gained several pounds in weight. After his relapse he soon got into his old condition, with incessant cough, pruritus, alopecia again almost universal, sleepless, pale, and ran along in about this condition until November, 1890, when all his symptoms became more distressing and his abdomen and lower extremities began to swell. The abdomen was tender and painful. During the winter he failed in every way, becoming considerably emaciated. He died in July, 1891. For some weeks before his death the abdominal swelling had subsided and the legs and feet were less dropsical. Whether or not he had fever during this latter course, which corresponded with a widespread invasion of general tuberculosis, we have no record, but during his stay in the hospital in the previous summer there were no disturbances of temperature.

At the post-mortem examination, held twenty-four hours after death, the body was emaciated, the lower extremities moderately edematous, and, with the exception of a very sparse growth of light hair on parts of the scalp, the body was entirely destitute of hair. The pubic, axillary, and superciliary hairs, as well as the eyelashes, had fallen out. There was no trace of beard and but little hair on the head. There were many abrasions, particularly upon the thighs and legs, caused by scratching. The various chains of lymphatic glands were all more or less enlarged. Some of the cervical glands and the axilliary glands on either side were of the size of a walnut. The inguinal glands were not much enlarged. On opening the chest, the heart was found to be normal. The mediastinum was literally packed with a great mass of large, roundish, and irregular tumors, clearly a huge growth of all the bronchial and other lymphatic glands of this region. They were matted together, so as to be very difficult of separation, but many were larger than hens' eggs. The pleural cavities were totally obliterated by adhesions, and the lungs were everywhere studded with tubercles of the size of grains of wheat.

On opening the abdominal cavity, no fluid was found, but all the organs of this cavity were bound in one mass by more or less firm adhesions, and the peritoneum was everywhere studded with tubercles, not of the finer or genuine miliary variety, but somewhat irregular bodies, from the size of sago-grains to that of small peas. As far as the eye could detect there were none of the millet-seed sized, whitish-gray, hard nodules, sometimes seen in acute miliary tuberculosis. These were larger, softer, and more caseous in appearance. The abdominal glands were all greatly enlarged, many of them varying in size from that of walnuts to that of hens' eggs.

The omentum was a thick, hard, nodular mass. The

liver was somewhat enlarged, everywhere adherent to surrounding parts, but it presented no visible tubercles in its interior. The capsule of the spleen was very thick and dense, and so intimately adherent to adjacent parts that it was extracted only after long and forcible tearing. The organ was considerably enlarged, but no tubercles were seen in its parenchyma. The kidneys were, like the other organs, firmly imbedded in the thickened peritoneum, but they appeared normal on section. All the internal organs of the chest and abdomen, excepting the heart, were bound into one mass by the adhesions.

The cause of death was general tuberculosis arising from tuberculous glands.

Among the occasional sources of pruritus, I believe Kaposi and others mention lymphadenoma or Hodgkin's disease, and it is perhaps not to be marvelled at that so protean a disease as tuberculosis should give rise to a great variety of symptoms. Probably no other specific infection, excepting the syphilitic, gives rise to such varied symptom-complexes as does the tuberculous. Outside of the pulmonary and other more ordinary manifestations, its ravages are often most curious. The autopsy not rarely yields surprising results.

A CASE PRESENTING THE SYMPTOMS OF LANDRY'S PARALYSIS, WITH RECOVERY.[1]

BY F. T. MILES, M.D.,
PROFESSOR OF PHYSIOLOGY AND CLINICAL PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM, UNIVERSITY OF MARYLAND, BALTIMORE, MD.

M——, a native of Baltimore, thirty-three years old, well-built, rather corpulent than muscular, temperate in all his habits, and accustomed to lead a very quiet life; had been in good health previously to the attack about to be described.

On November 26, 1891, he caught cold, for which he took quinine and mustard baths. On November 28th he got wet by rain. He now experienced intermittent pain in the calf of the leg. About December 1st he observed, to use his own language, "a cold feeling across his toes, as if he had dipped them in cold water; also the same cool feeling attacked the left upper lip [*sic*], as if it were chapped and air blew on it." These ill feelings continued till December 6th. On that day he was about the house, as usual; but in the afternoon, on attempting to go up stairs, in his own words, "very much to my surprise, I found I did not have the power to raise the left leg from one step to the other without serious exertion in the way of dragging it." In a few days he took to his bed, "being unable to hobble around any longer." The feeling of coolness and numbness continued to get worse, and to extend upward on his legs to the knees, and also invaded the hands and arms to the elbows, the muscular power steadily failing from the lower extremities upward.

The patient was under the care of Dr. F. Chatard, of Baltimore, who kindly asked me to see him, and to whom I am indebted for many details of the case. I first saw the patient on December 17th. His lower limbs were then completely paralyzed, but not emaciated or flabby. The muscles of the trunk and belly were greatly weakened. The man could make a wriggling motion with his hips, but could not sit up or turn on his side. He coughed, but with very little force. The hands and arms were quite weak, with a tendency to assume the position of wrist-drop. The shoulder-movements were good; the face was not affected. Sensation was apparently normal, except that the sensation of tickling on the sole of the foot was nearly or quite lost. The power of localizing correctly any point of the foot touched was retained. Farado-cutaneous sensibility was apparently normal. The man could distinguish hot and cold objects. No pain was elicited on pressing the muscles. The reflexes, both superficial and deep, were completely lost.

Tested with the faradic current, the muscles responded, as nearly as I could judge, normally. The patient's subcutaneous layer of fat was thicker than usual. To the galvanic current the muscles responded normally, contracting quickly without a sign of degenerative reaction, with no quantitative or qualitative alteration. The muscles also contracted from nerve-stimulation. The sphincters were absolutely intact. After this, for three or four days, the paralysis increased in the upper extremities until the man could no longer use his hands. The abdominal muscles became so weak that he could not cough. The facial nerves now became involved in all of their branches, the more decidedly, however, on the left side. The patient could not frown, could not close the left eye, could with effort barely approximate the lids of the right so as to make them touch, and could not whistle. Articulation was somewhat defective from the weakness of the labial muscles. The tongue was unaffected, except that the patient stated that it felt thick. He was restless, and said that he felt as if he was being smothered by his own weight.

The breathing became oppressed, and he had several attacks of threatened suffocation. (The action of the heart was not affected, either in frequency or force.) At this point the progress of the disease seemed to be arrested, and then improvement, especially of the respiratory symptoms, began and proceeded somewhat rapidly, the face and arm recovering first. On the 1st of January, 1892, he could raise himself in bed; on the 7th he sat up on the side of the bed; on the next day he dressed himself; on the 13th he was able to walk alone; and on the 20th he was able to leave the house. I saw him about a month later. His limbs were not thinner than natural, though still a little weak. The patellar reflex was still absent.

This case seems to me worthy of record, because of the very close resemblance of its symptoms to those of Landry's paralysis. Indeed, I do not see why it should not be considered as a case of that disease. It is noticeable that the symptom of oppression and difficulty in breathing that usually closes the scene in fatal cases of Landry's paralysis was prominent, and appeared to lack but little in severity to have caused death.

Dr. Cramer, in the January number of the *Centralblatt f. Pathologie u. pathologische Anatomie*, after having given an admirable analysis of the best-studied cases of Landry's paralysis, concludes that "with the symptom-complex that we call Landry's paralysis, the pe-

[1] Read at the seventh annual meeting of the Association of American Physicians, held at Washington, May 25, 1892.

ripheral nerves alone, as well as the central nervous system with the peripheral nerves, may be diseased" (the peripheral nerves being in almost every case affected); and, moreover, that the origin of the disease is to be found in the toxic influences of invading microörganisms. From this standpoint there seems to me but little difficulty in supposing cases of varying severity and termination, as the central nervous system (the respiratory and cardiac centers) or the nerves of respiration are more or less deeply affected by the toxic agent. One point seems to be impressed by this case—namely, the difficulty, or rather impossibility, in certain cases, of differentiating between the peripheral and central (spinal) origin of symptoms, especially of paralysis. I think we should keep more in mind that the whole motor system—peripheral nerves, nerve-cells, and central tracts—is so much of a unit, that while the insults of disease may confine themselves to one segment of the apparatus, we may reasonably expect disease of one part to extend to others or all.

MEDICAL PROGRESS.

Cysticercus of the Vitreous Body.—At a meeting of the Society of Physicians of Zurich FICK (*Corr.-bl. f. Schweiz. Aerzte*, 1892, No. 9, p. 279) reported the case of a man who, six months previously to coming under observation, noticed a black spot before the right eye; three months later, vision was distorted, and a month later still, became cloudy. For nine days there had been total blindness, only light-perception remaining. The external appearance of the eye was normal. With the ophthalmoscope two masses and some diffuse changes were found in the interior of the eye. One of the masses was a grayish-blue vesicle, with a well-defined reddish-yellow margin, occupying the lower posterior segment of the vitreous body and oscillating with sudden movements of the eye. Vessels could not be seen on the cyst. The second mass, bluish-gray in color, bean-shaped, was situated in the outer upper segment, and was sharply separated from a whitish band in the vitreous body. At the upper extremity of this mass was a whitish area abundantly supplied with vessels. The retina presented diffuse striation; the vitreous body punctate and striate immovable opacities.

The patient was operated on a few days later, and together with the removed specimen was presented at a subsequent meeting of the Society. Some improvement in vision had taken place.

An Unusual Case of Empyema.—RUDOLPH (*Centralbl. für klin. Medicin*, 1892, No. 18, p. 361) has reported the case of a shoemaker's apprentice, eighteen years old, who, twelve days after an attack of pneumonia involving the lower lobe of the left lung and lasting a week, developed pneumonia of the upper lobe of the same lung. After the fifth day of the second attack the febrile movement became irregularly intermittent and occasional chills occurred. Unequivocal signs of an empyema soon manifested themselves. An inch and a half of the seventh rib was resected and two pints of pus were evacuated and the cavity was from time to time irrigated. There was some improvement, but the febrile movement persisted. The signs pointing to the existence of an encapsulated empyema above the situation of that first detected, a little more than an inch of the third rib was resected and four pints of pus evacuated. There appeared to be absolutely no communication between the two cavities. The patient ultimately made practically a perfect recovery; this was somewhat retarded, however, by the presence of a fragment of carious bone in one of the resection-wounds.

Conveyance of Tuberculosis by Bed-bugs.— DEWÈVRE (*Revue de Méd.*, No. 4) reports the case of a boy, eighteen years old, who developed pulmonary tuberculosis after having slept with a brother who had died of the disease. A third brother, with whom the second had slept, had likewise died of tuberculosis. The patient presented numerous bed-bug bites, and it was learned that the bed in which he slept contained a large number of the parasites. Thirty of these were taken and used in the inoculation of three guinea-pigs, all of which died of tuberculosis. Cultures of tubercle-bacilli were also obtained from the diluted and filtered pulp of fifty of the bugs. Cultures were also obtained from bugs taken from healthy surroundings and brought into contact with tuberculous sputum. The bugs must become infected directly from human beings, or indirectly through the medium of the expectoration, or by transmission from one animal to another. The transmission of tuberculosis from the bugs to the human beings remains an open question.—*Wiener medizin. Presse*, 1892, No. 62, p. 90.

Fatal Hemorrhage from the Esophagus in Cirrhosis of the Liver.—At a meeting of the Berlin Society for Internal Medicine, EWALD (*Berliner klin. Wochenschr.*, 1892, No. 23, p. 566), reported the case of a man, fifty years old, with symptoms of advanced cirrhosis of the liver, who shortly after the removal of fourteen quarts of ascitic fluid by puncture, suddenly, without pain or nausea, began to vomit blood. The hemorrhage was repeated, and on the following day death took place. In the absence of nausea, of actual vomiting, and of pain in the region of the stomach, rupture of an esophageal vein was suspected. At the autopsy the liver was found cirrhotic, the esophageal veins dilated and varicose and ruptured in two places. It would seem as if the removal of the pressure upon the abdominal veins by the evacuation of the peritoneal effusion had been followed by the presence of an increased volume of blood in the esophageal veins, which ruptured at the weakest points.

Treatment of Lupus with Tuberculocidin.—At a meeting of the Society of Czech Physicians of Prague, JANOVSKY (*Wiener medizin. Presse*, No. 19, p. 779) presented three of four cases of lupus under treatment with tuberculocidin administered subcutaneously and applied topically. In all, thirty injections had been made without noteworthy constitutional manifestations. In only one instance did the temperature rise as high as 100.4°. There was no visceral affection; albumin did not appear in the urine; the blood presented a state of slight leukocytosis. The local reaction was considerable, though by no means so intense as that which followed injections of tuberculin. Small and large pustules formed in the diseased areas, afterward undergoing desiccation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 9, 1892.

THE CHEMICAL PATHOLOGY OF THE INFECTIOUS DISEASES.

THE problems of physiologic chemistry have heretofore been so baffling, and the solutions so unsatisfactory, that it is but little wonder that so few investigators have been attracted to the field of chemical pathology. The coarseness of the most delicate methods of investigation at the disposal of the chemist, compared with the extreme complexity of the substances with which he has to deal, the instability of the proteid bodies, the impossibility of determining the exact composition of the albumin-molecule, the difficulty in isolating pure materials—all these conditions offer serious obstacles in this study, and beyond the grouping into classes of the proteid bodies and their derivatives, little can be said to have been definitely determined. Despite all this, such researches have received a decided impetus from quite an unexpected quarter. Of late, special attention has been devoted to the examination of the more intimate relations between the specific microörganisms and the tissues of the body in acute infectious diseases; and perhaps the most interesting contributions to our knowledge of these processes during the past two or three years have been those dealing with the subject rather from a chemical standpoint.

The experiments of ROUX and YERSIN, in France, and of BRIEGER and FRAENKEL, in Germany, with the chemical products of LOEFFLER'S bacillus; the work of HANKIN on the "defensive proteids;" the action of the toxine and the production of the antitoxine of pneumonia, elaborated by the KLEMPERERS, of Berlin; the study of the chemical nature of tuberculin, by HUNTER, BEHRING, and others; the very striking effect of the proteins of the protoplasmic bodies of the bacteria themselves, demonstrated by BUCHNER and his assistants, at Munich—these and other similar researches, even though they have as yet yielded but few practical results, have opened up a wide field for speculation, and go far to illumine some of the possibilities of the intelligent application of chemical methods to pathology.

The latest, and by no means the least valuable, of such communications will be found in the Gulstonian lectures recently delivered by DR. SIDNEY MARTIN, in which he takes for his subject, "The Chemical Pathology of Diphtheria Compared with that of Anthrax, Infective Endocarditis, and Tetanus."

In his study of anthrax-infection, DR. MARTIN had already shown that the action of the anthrax-bacillus on proteids is analogous to that of the ferments of the ordinary digestive juices, resembling peptic digestion in the formation of albumoses, and tryptic digestion in that a portion of the proteids is broken up into non-proteid organic bodies, the leucin and tyrosin obtained as end-products from the action of trypsin being represented in anthrax-digestion by an organic base, the so-called "anthrax-alkaloid." These digestion-products of the anthrax-bacillus were found not only in test-tube cultures of the organism, but also in the blood, and particularly in the spleen, of animals that had succumbed to the disease, and it is important to note that the alkaloid was always more abundant than the albumoses. It was possible to separate the alkaloid from the albumoses, and by injecting these substances, singly and together, to compare the symptoms thus artificially produced with those characteristic of the disease. In this way it was proved that the albumoses are the fever-producers, while the anthrax-base (alkaloid) is the cause of the coma and death.

DR. MARTIN devoted the greater part of his recent lectures to the discussion of the chemical products found in the bodies of diphtheria-patients, the methods of isolating them, and the symptoms and histologic lesions to which they give rise. Briefly,

he concludes that the tissues of diphtheria-patients contain two series of abnormal substances: first albumoses, chiefly deutero-albumoses (indistinguishable chemically from the albumoses of ordinary digestion and from the anthrax-albumoses), and secondly, an organic acid, the former being present in larger quantity than the latter. Of the diphtheria-poisons, in contradistinction to the toxic products of anthrax-infection, the albumoses are much more harmful to the animal than is the non-proteid substance. A single dose of the albumoses of 0.084 gram per kilogram of body-weight, injected subcutaneously in a rabbit, caused death in twelve days, and at the autopsy the degenerative changes characteristic of the disease were present.

If these results are to be relied upon, and the experiments appear to have been carefully and conscientiously conducted, then it is to the albumoses in diphtheria that we must attribute the fever, the diarrhea, the loss of body-weight, the retardation of blood-coagulation, and the progressive paralysis of the muscles dependent on degeneration of the peripheral nerves. The injection of the organic acid, it is claimed, produces nerve-degenerations similar to those resulting from albumose-intoxication. There would appear to be some evidence for the view that the immediate action of the *bacillus diphtheriæ* in the membrane is to give rise to a ferment—the so-called secondary infectious agent—quite analogous to the pepsin and trypsin of the gastric and pancreatic juices, for while on chemical analysis the membrane itself is shown to contain very minute quantities of the albumoses, yet a single injection of the proteids precipitated from it will produce results like those obtained from multiple inoculations with the albumoses. The claim of DR. MARTIN, that the same nerve-lesions are produced by the albumoses and the organic acid of diphtheria would seem to require further proof, as there would always exist a possibility that such degenerations might be due not to the albumoses or to the acid, but rather to a toxic agent as yet unknown, most of which is precipitated with the albumoses, while a small portion passes over in the alcoholic extract.

In all the cases of diphtheria, natural and experimental, the central and peripheral nerve-organs were submitted to careful histologic examination; lesions were always found in the peripheral nerves, motor, sensory, and sympathetic, and were as constantly absent in the central organs and large nerve-trunks. Sometimes there was a transverse degeneration of a small nerve, with destruction of its axis-cylinders, when in life there had been complete paralysis of the muscle supplied by the nerve; more often individual fibers were affected, while their neighbors remained intact. Such a condition readily explains the many forms of paresis, or incomplete paralysis, so often met with clinically. A fatty degeneration of the voluntary muscles takes place *pari passu* with the lesions in the nerves supplying them. The heart-muscle was always fatty, even though no change were discoverable in the branches of the vagi going to it, and it is assumed that the fatty changes there must have been due either to the altered blood-condition or to the diphtheritic digestion-products acting as direct cardiac poisons. DR. MARTIN has not only confirmed the researches of DEJERINE and of MEYER, but has carried them still further, and it is almost inexplicable to us how so careful an observer could overlook the changes in the lymphatic apparatus and supra-renals; whereas, in these organs, which he describes as normal, decided retrogressive changes have been found (WELCH and FLEXNER, 1891).

The material available for the chemical study of infective endocarditis and of tetanus was very limited, only one case of each having as yet been examined. What has been done, however, would make it appear that in infective endocarditis the products resemble those of anthrax-infection, while in tetanus they more nearly approach those of diphtheria. This is exactly what might have been expected, since in anthrax and infective endocarditis the organisms invade the tissues generally, while in diphtheria and tetanus the organisms remain at the site of inoculation.

We must regard as in the highest degree ingenious the theory as to the rôle played by the spleen in the pathologic process. The tissues of this organ always contained relatively large quantities of the poisons, and the idea is advanced that the spleen is to be looked upon not only as the depository, but also as the chief manufactory for them, the explanation being that the blood leaving the vessels in the spleen-pulp runs out into the sinuses among the cells, whence results a condition of stagnation. The microörganisms in anthrax and in infective endocarditis, and the ferment (absorbed from the local lesion) in diphtheria and tetanus, find there a quiet spot in which to exercise their digestive functions, and convert the proteids first into hetero-albumose, and later into proto-albumose and deutero-albumose,

with the formation of by-products, which last have in some cases an alkaline, in others an acid reaction. In like maner pathologic effusions previously present in the body, or those produced in the course of the disease, afford (it is thought) a suitable medium for the increase of the infective agents themselves, and for the formation of their digestion-products, since in such effusions proteids are held in a slightly alkaline solution, and are removed from the active metabolic processes of the body.

It would seem, therefore, that just as there is a specific primary infective agent, so there are no less specific chemical products for each disease. These products are distinguishable to a certain extent chemically, but to a far greater extent by their physiologic action. Thus, we have a further means of deciding which is the genuine primary infective agent in a given disease, and DR. MARTIN suggests that to the four rules of KOCH there be added a fifth, namely, that "The chemical poisons must be obtained from the tissues in the natural disease, and products with a similar physiological action proved to be formed by the primary infective agent when grown outside the body." In a disease like Asiatic cholera, which is constantly associated with the comma-bacillus, but in which the application of all of the four requirements of KOCH is at present impossible, the fulfilment of this fifth requirement would afford valuable confirmatory evidence in settling the question of etiology.

The fact mentioned in the closing lecture, that in these experiments no antitoxine was produced in the test-tube cultures of any organism, is merely negative, since the supporters of the theory of antitoxine-formation have not claimed that these substances are manufactured save through the direct action of the living blood-serum.

On reading these lectures we cannot help feeling hopeful as to the future of chemical pathology, although we must not be too sanguine, since the best organic chemists of the day regard the theories based upon the supposed nature of the proteid substances as mere conjectural hypotheses.

SEXUAL HYPOCHONDRIASIS.

IN addition to the large number of cases presenting themselves to the physician for the relief of various real disorders of the genito-urinary apparatus, there is another group, including a portion of the first, the constituents of which manifest great perturbation of mind in consequence of some imaginary affection of the generative system. The greatest number of this second class is made up of males at the period of adolescence.

The two most important, if not the sole, factors that lead to the condition under consideration are masturbation and excessive venery. The patients often present the peculiar aspect and behavior of conscious guilt by which the clinician is sometimes at a glance able to divine the diagnosis.

The more common symptoms of which the patients complain are a "loss of ambition," an inability to concentrate the mind, a sense of weakness, a "lightness in the head," disturbed sleep, impaired appetite, and deranged digestion. Sometimes a patient who has familiarized himself with the popular literature on the subject (of which there is a pernicious superabundance) will frankly volunteer the information of his excesses; another will complain of nocturnal or even diurnal seminal emissions or of other derangement in the sexual sphere. Very often morbid fears have been engendered by the vivid descriptions of unscrupulous persons skilful in the art of playing upon the imagination of the credulous. Visions of "lost manhood," of impaired virility, etc., float before the victim's eyes, and in despair at the failure of the nostrums that promised certain relief, he comes to the physician requiring treatment rather for a diseased mind than for a diseased body.

It will depend upon the skill and insight of the physician whether he shall accomplish an apparently marvellous cure or confirm the direst anticipations of the unfortunate patient. Success in treatment will not depend upon the administration of drugs, nor as a rule will argument convince the patient of the falsity of his absurd notions. He must be convinced and cured by the logic of demonstration.

The most important factor in treatment is support of the morale. The nervous system will require close attention. The condition is probably one of reactive depression with irritability. Sedatives are not so much demanded as stimulants. Of course, the mode of life must be regulated. We are convinced that if in these cases in males the rest-cure could be carried out as it is in their female analogues it would yield the same brilliant results.

Regularity is essential as to meals, as to sleep, as to occupation. Thought and association must be purified and made cheerful, healthful, and con-

genial. The patient must be taught to lose his consciousness of self. The cold bath, followed by thorough friction, is the best stimulant. Walking and other out-of-door exercise is a most useful expedient. It need scarcely be said that when organic lesions are present these should, if remediable, be corrected. The medicinal agents that seem to do the most good are arsenic, phosphorus, and strychnine.

SELECTION.

THE VITALINE CRAZE.

To call it consternation is not too strong a term; for although we do not accredit the statement that ten thousand people in Russia have received injections of the stuff "vitaline," there is without doubt a panic on the subject of this injection—this most absurd so-styled "rejuvenator" of old idiots and antidotal preserver of young ones. The story of the "discovery" of this "new remedy" is an old story revived. A wanderer from his native land, this time one Gatchkowsky, an engineer, was sent on his own business into the Trans-Caspian territory, and there, amongst a primitive people, he heard of a new specific. "A Chinese *savant*" revealed to him the particulars of a miraculous compound medicine which, being instilled into the blood of man, would cure everything; it was more than a mere panacea; it was a "rejuvenator," a curer of such fatal diseases as consumption of the lungs without fail. All previous wonders were to be surpassed by it, and the scientific world was once more to be set in commotion by a discovery that should show how natural law in disease could be overthrown in wholesale fashion. For a time—happily short, yet long enough—the new practice made its way, and we are told the regular practitioners of medicine in St. Petersburg were dumfounded by the presence of the "tide of fashion and of favor" that set in. To some invalids, real or supposed, the "vitaline" was administered by injection subcutaneously; to others it was administered internally. Prices for the remedy and its application varied; the rich paid largest fees, but the poor also paid, and some of them also largely. The Czar himself was counselled—by whom is not known, but we should suppose not by any authorized medical adviser—to let his son, the Grand Duke George, undergo the treatment. At last a somewhat less important man, but still one of great importance, was subjected to the remedy, and he, General Gresser, the Prefect of St. Petersburg, and one of the firmest and shrewdest of the guardians of the imperial power, was led to submit himself to the operation, and by the submission sacrificed his life. How, precisely, the sacrifice was brought about we have as yet no satisfactory details. The discoverer of "vitaline" turned round in his defence from the sublime to the ridiculous. The omnipotent remedy at once diminished from its potency into a mere mixture of borax and glycerin—a harmless mixture for good or for evil. If death resulted from the use of it, a dirty syringe used for the injection must have been the true cause; but M. Gatchkowsky, having made a clean breast of his discovery, will practise the art of cure no more; and if he be not, in the panic, charged with political offence and of systematically poisoning the Prefect, he is fortunate. The history of this latest blast of quackery recalls some of olden times which it has been the duty of *The Lancet* to expose and trample out. The case of the notorious St. John Long comes at once to mind. In this case the results which followed the practice of the astute quack were practically the same as those we have just witnessed. What is more, the secret, which Long sold, as was reported, for £3000 to a lady of fashion, turned out, in the end, to be no secret at all. The element of treatment was counter-irritation, and the vaunted composition employed as a liniment was nothing more and nothing less than spirit of turpentine and strong acetic acid. One day the famous nostrum went wrong in its action; it caused, or was accused of causing, a diffuse cellulitis in an unfortunate victim, and then not only was its fate sealed, but in defence the secret was exploded in proof of its harmlessness and its perfect simplicity. Against this specimen of quackery the founder of *The Lancet* fought tooth and nail. He neither hesitated nor paused until the mischievous practice was expelled for good. In this fight, moreover, he had not the whole voice of the profession with him. On the contrary, one man in the profession stood by the delusion to the last, and vainly maintained his advocacy of it after the bubble had burst and its inventor with it. It is our business still to expose, and protest against, these frauds on humanity, exploited as they are at the risk of human suffering and death.—*Lancet.*

REVIEWS.

A MANUAL OF OPERATIVE SURGERY. By FREDERICK TREVES, F.R.C.S. Two volumes, octavo, pp. xvi, 775; xviii, 775. Philadelphia: Lea Bros. & Co., 1892.

JACOBSON, GREIG-SMITH, and TREVES, form a triumvirate of which English surgery may well be proud. Mr. Treves's handsome work has been on our office-table for some time past, and we have consulted it repeatedly, and almost always with great satisfaction. It lacks the admirable and trustworthy indications for treatment, and many of the little practical hints that Jacobson gives. It is not so full in detail, nor yet so limited in scope as Greig-Smith, but it shows on every page the practical and experienced surgeon, whose anatomy is a help, and not a hindrance to his surgery, and who thoroughly understands surgery as a handicraft. It is a book born of experience, and enlarged by wide judicious reading. In fact, it is a great pleasure to note that the three gentlemen whose *Surgeries* have been alluded to, have culled from every part of the surgical field, and have shown a just appreciation of the excellent work done by American surgeons. In this respect this work is a happy contrast to most of the Continental *Surgeries*, which scarcely turn their eyes toward the West.

Mr. Treves's book opens with some excellent general principles. He shows occasionally a sententiousness and an epigrammatic turn of expression that are admirable. In enumerating the qualifications of the "skilled handicraftsman," he says: "A shakiness of the hand may

be some bar to the success of an operation, but he of a shaky mind is hopeless. In the holding of a sharp instrument in connection with the human body, a confusion of the intellect is worse than chorea." Again, he well puts the question of the length of incision as follows: "Surgeons who boast of the smallness of their incisions are proud of what is at most a questionable feat. . . . There can be no possible object in attempting to ligate the common carotid through an incision an inch long. It can be done as a feat; as a surgical procedure, it involves much cutting in the dark, and adds quite unnecessary danger to the operation."

We notice that he gives very little space to the directions for antiseptic surgery, which seems to us a mistake of omission. Mr. Treves calls attention to the object of sutures, that this is not to close the cut in the skin only. "The main wound," as he says, "is represented by two large *raw surfaces* which lie beneath the integument." Hence, the obliteration of the wound-cavity, rather than simply sewing up the rent in the integument, is what is to be aimed at. Again, in drainage we observe that he urges that drainage-tubes should be removed in twenty-four, or at most thirty, hours after the operation. To leave them longer, as a rule, means simply to create a sinus. His practical sense shows itself in his advice to keep the wounded part uncovered by the bed-clothes, since the atmosphere under the bed-clothes "is hot and moist, and frequently foul, as after the use of the bed-pan and escape of flatus. If there be any truth in the principles which underlie antiseptic surgery, no atmosphere could be worse for a wound." It is interesting to note that he gives proper credit to Physick, of Philadelphia, for having introduced animal ligatures in 1814.

As a rule, he shows a judicial mind in weighing the advantages and disadvantages in different operations or different methods of operation. He is not too positive when there is much to be said on two sides, and yet he is not lacking in decision. For instance, in the operations of lumbar and iliac colotomy, he gives the advantages and disadvantages of each operation, and then, without being dogmatic, says that he for one is disposed to agree with Mr. Bryant in his final conclusion in favor of lumbar colotomy. We note, by the way, that he says the more precise terms would be *colostomy* for a permanent, and *colotomy* for a temporary opening. It would seem at the present day desirable that the nomenclature of these operations on the colon should be made to conform with other similar names, such as gastrotomy and gastrostomy, enterotomy, and enterostomy, etc. It is noticeable, also, that he correctly spells a name so often incorrectly written, viz: Littre. This is correctly given without the accented "é," although so good an authority as Billings, in the *National Medical Dictionary*, spells it with the accent.

We are very glad to observe that he takes strong ground in favor of the intra-peritoneal treatment of the stump after hysterectomy. The statistics of this method will, before long, have to be recast, and we have no doubt that, with the modern means that have been introduced, it will very soon show percentages of recoveries surpassing those of the obnoxious extra-peritoneal treatment.

In the section on operations on the rectum, we are rather surprised to see no mention made of either Kraske's operations or the various modifications by Hochenegg, Bardenheuer, or Rose. In the operations on the brain, the cut of Hopkins's rongeur forceps is certainly incorrect, if it is meant to figure the well-known rongeur of the Philadelphia surgeon.

A few matters in which this book could be slightly improved we have pointed out. On the whole, it is one of the best books descriptive of surgical technique that we know, and we can confidently commend it to the profession as one in which the surgeon will almost always find precisely what he desires to know from the operative point of view.

THE PATHOLOGY, DIAGNOSIS, AND TREATMENT OF INTRA-CRANIAL GROWTHS. By PHILIP COOMBS KNAPP, A.M., M.D. (Harvard). Fiske Fund Prize Dissertation, No. XLI. Boston: Press of Rockwell & Churchill, 1891.

THIS volume affords one of the best illustrations and examples of the usefulness, advantages, and value of trustee prizes, and of the necessity that exists for them, or their like and counterpart, to bring out the best exertions of which some men—some of the best workers—are capable. Many such men are all the while the best of workers, or capable of the very best work, and yet fail to give it to the public, not because the work has not been performed; not from lack of opportunity or thoroughfare of communication, but from lack of incentive, from want of occasion or of the subject or of the point of direction.

Would that more such "suggestive" prizes existed among us! That other fields of work than medicine attract most able workers, giving prizes in fame and fortune beyond compare, is true. Nevertheless, medicine sees a constant stream of workers of ability equal to that of these others who would content themselves with the modest fame coming from prizes like this one, and men withal who would willingly await the modest rewards that at the best are likely to accrue to the most successful of the medical profession.

The book itself, as by the necessities accompanying its prizeship, is most admirable, and it contains, with the accompanying references and tables, the essentials requisite for anyone attaining to a full, a thorough knowledge of the question in hand.

The subject of "brain tumors," as in times past it was named, but now, in the era of operative treatment, better spoken of as "brain pathology," as "intra-cranial lesions," has had a most picturesque and most graded process of development. Symptomatologically the advance has been probably more strikingly conspicuous than in any other lesion of the organism.

In literature the subject exhibits even more sharp demarkations. Before 1850 all observations of intra-cranial gross lesions were most diffuse, if not also most vague. From 1850 to 1860 gave us the period of symptomatology. From 1860 to 1870 inaugurated the exactitude of diagnosis by means of the ophthalmoscope; it is Von Graefe to whom we turn with thanks for this development.

To-day it is—from 1870 onward—that we see the symptoms of localization definitely studied — so very definitely that the surgeon's knife may reach the seat of

the growth and perhaps remove the mass. Whether or not the results are to be distinctly and as definitely beneficial the following decade is to be the sole judge.

Of the literature, of the clinical records of brain tumors, Ladame, in his volume, *Symptomatologie und Diagnostik der Hirngeschwülste*, has collected very nearly completely all the records until 1860. The present volume does not cover with as great thoroughness the localization and operative period (1870–1880) as does Ladame's work; perhaps such completeness of compilation is no longer possible, so great has become the mass of clinical records.

The period of the ophthalmoscopic study—which today seems somewhat neglected, even for routine diagnostic work—has not as yet been given. It is much needed to complete the essentials of brain pathology. Should Dr. Knapp wish to prosecute the labor he has so very well begun, the writer of this review is able to put him in possession of a complete collection in manuscript form of all the cases of brain tumors confirmed by a post-mortem examination published during the period from 1860–70.

A Text-book of Nursing. For the Use of Training-schools, Families, and Private Students. Compiled by Clara S. Weeks-Shaw, Graduate of the New York City Hospital Training-school for Nurses. Second edition, revised and enlarged, with illustrations. New York: D. Appleton & Co., 1892.

This book first appeared about six years ago, and is the best text-book for the general instruction of nurses that we have. The present revised edition was much needed in order to keep the work in touch with the latest methods of teaching in the medical profession, particularly in antiseptic surgery, and the additional chapter on gynecology fills a want that was much felt in the previous edition. The subject-matter of the book is especially adapted for hospital nursing, and the order of subjects is carefully arranged in twenty-five chapters, beginning with the simplest and those requiring to be taught first.

If anatomy and physiology are taught in connection with the use of this text-book, as the author advises, the repetition of the anatomy of the heart, lungs, and blood-vessels and the description and classification of the bones would hardly seem necessary.

The book deserves to be in the possession of every trained nurse and in every training-school library.

Lehrbuch der Auscultation und Percussion mit besonderer Berücksichtigung der Besichtigung, Betastung und Messung der Brust und des Unterleibes zu diagnostischen Zwecken. Von Dr. C. Gerhardt, Professor der Medizin und Geh. Med.-Rath in Berlin. Fünfte, vermehrte und verbesserte Auflage, mit 49 in den Text gedruckten Holzschnitten. Tübingen: Verlag der H. Laupp'schen Buchhandlung, 1890.

In the preface of this, fifth, edition of his work, Gerhardt says: "Wherefore percuss? We can stain sputa, and by the number of bacilli not alone recognize the existence of phthisis, but also observe its progress. Those who will delight only in the new, yea in the newest, might accept this dictum with satisfaction. He who seeks for a means of complete diagnosis of the many-sided morbid processes, will not omit the exploration methods of Laennec and Skoda, but will learn from extended use more and more to prize these, the most solid foundations of our diagnostic art."

The book is too well and too favorably known to require extended review at the present time. It has been enlarged and enriched with the recent fruits of the author's wide observation. It deals not only with the lungs and heart, but with the whole organism, and it systematically and thoroughly discusses the whole subject of diagnosis by means of sound, giving the physiologic, anatomic, and acoustic groundwork of theory and methods, and the experiential lessons of pathology and clinical observation as to the diagnostic value of the signs thus elicited.

While the author has diligently studied the works of others and gives them due credit, yet the book is stamped throughout with the impress of original thought and independent observation. No one who aims to be thoroughly informed upon the subject can afford not to study it.

Lectures on Pathology, Delivered at the London Hospital by the Late Henry Gawen Sutton, M.B., F.R.C.P. Edited by Maurice Eden Paul, M.D., and revised by Samuel Wilks, M.D., LL.D., F.R.S. Philadelphia: P. Blakiston, Son & Co., 1891.

The book consists of a number of clinico-pathologic discourses on a great variety of subjects. The title does not indicate the scope of the work as well as did that of a previous book by the author on "Medical Pathology," the greater part of which is here reproduced. Of the fifty-two chapters or lectures we may name those on Anemia, Struma, Smallpox, Dysentery, Gonorrheal Rheumatism, Purpura, Typhoid Fever, Diabetes, Kidney Diseases, and Heart Disease, as indicating the wide scope of the work and the character of subjects discussed. Though we may be disposed to agree with the editor that the book will be more acceptable to Dr. Sutton's former pupils, published as it is as nearly as possible in his own words, we cannot agree that this was the best plan, when other readers are considered. There is something gained, but more lost.

These lectures contain an immense fund of clinical observations, which are of all the more value since, at every step, clinical facts are traced back to their pathologic foundation. It is the living active pathologic teaching of the clinician, rather than that of the anatomist, which is here detailed. It is a matter of great regret that death prevented the revision of the lectures by the author, since many of them were delivered several years since, and doubtless much would have been altered. Particularly would it have been desirable to obtain a definite expression in regard to the relation of bacteria to disease, a question that will scarcely be considered settled by this generation of readers in the conservative manner in which the lecturer regarded it.

The Langenbeck-Haus, intended as the meeting-place of the various medical organizations of Berlin, was opened on June 8, with appropriate ceremonies.

SOCIETY PROCEEDINGS.

THE AMERICAN ASSOCIATION OF ANDROLOGY AND SYPHILOLOGY.

Sixth Annual Meeting, held at Richfield Springs, N. Y., June 21 and 22, 1892.

FIRST DAY—JUNE 21ST.

DR. GEORGE CHISMORE, of San Francisco, read a paper entitled "A New Form of Lithotrite and Aspirator, with Cases Illustrating Their Use." The instrument exhibited consists of a combined crushing and evacuating lithotrite. The male blade is solid, and furnished with Bigelow's lock and screw power, both fitting the same female blade. The male blade has a channel of sufficient size to enable the aspirator to suck pieces of stone into the open jaws, yet leaving metal enough to allow the application of the screw. The wash-bottle consists of a rubber-bag so shaped as to comfortably fit the hand and a glass reservoir. Dr. Chismore then gave the history of ten cases of stone in the bladder operated on by the method described, in addition to fifty others reported to the Association at a previous meeting.

DR. L. BOLTON BANGS, of New York, stated that he was much interested in the form of lithotrite presented. He noticed that the instrument was non-fenestrated, and thought that there might be some danger of catching the wall of the bladder in closing the blades. He considered the wash-bottle shown a most useful one, and extremely simple.

DR. JOHN P. BRYSON, of St. Louis, thought the operator could recognize very quickly whether any of the bladder was caught in the instrument. Besides, the female blade projects for a considerable distance beyond the male blade, and thus acts as a safe-guard. He considers the simplicity of the wash-bottle one of the chief advantages of the instrument. This obviates the constant removal and re-introduction of the instrument, as a result of which the prostatic sinus of the urethra is likely to be bruised. Finally, the instrument renders the operation easier, and places it in the hands of the general surgeon. He has seen supra-pubic cystotomy performed a number of times for stones that could have been removed more easily by the lithotrite.

DR. ARTHUR T. CABOT, of Boston, stated that he seldom uses a lithotrite with a fenestrated blade. He habitually employs Bigelow's instrument, with the solid female blade. In crushing a phosphatic stone with a fenestrated instrument fragments of the stone are likely to be thrust through the female blade, and thus hinder the operation. With the solid blade there is less likelihood of injury to the bladder-wall. Dr. Cabot considers Dr. Chismore's arrangement an excellent one for crushing small fragments of stone.

DR. W. K. OTIS, of New York, described "The Perfected Electro-Urethroscope," which represented a further improvement of the modification of the Leiter instrument for urethral inspection, shown at a previous meeting of the Association. A plain lens has been substituted for the mirror formerly employed, making the instrument less expensive, and shutting off all extraneous light. A small electric lamp is employed for illumination.

DR. E. R. PALMER, of Louisville, Ky., presented "A Contribution to the Physiology of Sexual Impotence." He divided his subject into two sections, namely (1), physiologic impotence of the male, without any regard to sterility, and (2) physiologic impotence of the female, with a like disregard of her procreative powers, avoiding as far as possible all of the many pathologic influences and effects that are recognized by the profession in this connection. He ascribed the impotence of youth largely to the common misconception with which the emission of semen is viewed. The youth is taught that semen is a marvellous product, a thousandfold more precious than even blood itself. This popular doctrine, Dr. Palmer considers an egregious error and a blunder unwarranted either by analogy or by fact. There is no evidence that in the regular use of the testicles, they, like glands and organs generally, are not developed and strengthened, rather than weakened and exhausted. Dr. Palmer contended that within reasonable bounds the regular and frequent use of the sexual organs tends to an increase of their power, while irregular use and continence are in many cases of sexual failure hurtful. The impotence of youth is the impotence of inexperience rather than of incapacity.

Turning from the physiologic impotence of the male youth Dr. Palmer took up the question of sexual failure in otherwise healthy men in the prime of life. Here again is to be met and combated the common explanation, "You are reaping the fruits of self-abuse, or the excesses of your early life; you have, by one or both of these means, worn out your precious powers, and there is no hope for you." Among the ranks of these are many that not only were not addicted to excessive self-abuse in boyhood, and were not libertines in later years, but justly enjoy the reputation of being moral family men. These cases include a not inconsiderable number of passionate men; others that fear a waning of their powers and begin to practise conservative continence; and still others that are absorbed in business cares and worries during the day.

Dr. Palmer held essential the study of the maid, wife, and mother from the standpoint of physiologic impotence. The ideal young woman is almost necessarily impotent. From time immemorial the prerequisites in her moral and social qualifications have been modesty and chastity. That a universal law, acting through ages, calling for unquestioned chastity in maid and mother, should have had its effect in a large proportion of the sex in modifying the sexual organs and desires, is not surprising; that it has not absolutely extirpated feminine sensuality is perhaps more surprising.

In conclusion, Dr. Palmer stated that the primarily ruling causes in sexual impotence and incompatibility to-day are evolutional in nature. The influence of heredity has made man abnormally and perversely sensual, and woman sluggish to a degree little short of absolute incapacity.

DR. BRYSON expressed the belief that the man never lost any of his sexual power by abstinence.

DR. CABOT stated that in regard to men engrossed with business cares there is a general nervous exhaustion, involving also their sexual powers.

DR. SAMUEL ALEXANDER, of New York, read a paper entitled "Congenital Deformity of External Female Genitals, Entire Absence of Urethra; Spontaneous Dorsal

Dislocation of the Hip as the Result of Efforts to Retain Urine; Correction of Deformity and Restoration of Urethra by Plastic Operation; with Some Observations Upon the Technique of Urethral Catheterism." The patient was a girl fifteen years old, born without urethra, the bladder opening just below the pubis by an orifice sufficiently large to admit the little finger. There was incontinence of urine, except when the legs were strongly adducted. At birth there was no other malformation, and until the age of eleven the hips and legs were symmetrical. Four years ago the girl was kicked on the left buttock. Lameness became marked, and the left thigh became strongly adducted and flexed upon the trunk. On March 21, 1892, Dr. Alexander performed a plastic operation to restore the urethra, the ureters having been catheterized a few days previously as a preliminary step. The operation consisted in making a new urethra and in bringing together the upper portion of the labia majora so as to cover the orifice of the new canal. The urethra was twisted upon itself and stitched in place by uniting a portion of its margin with the vaginal septum. Two subsequent sittings were required to satisfactorily complete the operation. As a result the girl has control over her urine at all times, and can retain it for four hours during the day and for eight hours at night. By uniting the upper portion of the nymphæ, the vaginal orifice was not closed, and yet the necessary pressure for the urethra was obtained. In referring to the mechanism of micturition and the cause of the desire to pass water, Dr. Alexander stated that his own observations have led him to adopt the views of Guyon and others of the Necker School, that the contraction of the wall of the bladder is the principal cause.

Dr. A. T. Cabot, of Boston, reported a "Case of Sacculated Bladder, with Autopsy." The patient was a man, fifty-seven years old, who first presented himself in November, 1889, suffering with symptoms of stone in the bladder. A few days afterward a stone weighing 116 grains, composed of uric acid and urates, was removed by litholapaxy. The man made a good recovery. In March, 1891, he reported that, although much improved after the first operation, he was not entirely relieved of his symptoms. After a perineal incision the finger could touch a little rough stone high up on the posterior wall. It being impossible to dislodge it, a supra-pubic opening was made, through which the stone could be readily reached. It was about the size of an English walnut, and was contained in a pocket, the neck of which was not larger than a small pencil. The stone was broken by the forceps and removed piecemeal. About April 6th, the urine, which had hitherto been abundant, began to diminish in quantity; it contained a little pus, but no casts were detected. In spite of all efforts the man gradually failed, and died about six weeks afterward. At the autopsy, two pockets of the bladder-wall were found; they were arranged symmetrically, one associated with each ureter, lying a little above and outside of it. One of these pockets had contained the stone previously removed. A number of smaller pockets were also discovered. These pockets, Dr. Cabot said, were probably congenital. The right kidney was found shrunken and in a state of interstitial nephritis, associated with a pyelonephritis, and this condition led to the fatal result.

Dr. Bangs reported a case of sacculated bladder, in which the patient (who had suffered for several years with retention of urine), in attempting to relieve himself, suddenly experienced a sense of relief, and at the same time felt a pain in the abdomen. He died before an operation could be undertaken. At the autopsy, the bladder was found hypertrophied, with minute sacculi in the bladder-wall, a number of which contained stone. One of these sacculi had ruptured.

Dr. Bryson referred to the fact that in cases of acquired sacculi the muscular coat of the bladder separates, and the mucous coat sinks in, and a hernia of the bladder-wall results.

Dr. Robert W. Taylor, of New York, read a paper on "The Pigmentary Syphilide." He stated that the primordial pigmentary anomalies due to syphilis consist essentially in a hyper-pigmentation, which may in whole or in part be replaced by a corresponding loss of color or leukodermatous condition. This primordial hyperpigmentation is the essential pigmentary syphilide. All other discolorations are secondary processes, and are not to be classed as pigmentary syphilides. The pigmentary syphilide is seen in three well-marked and quite distinct conditions: 1. As spots or patches of various size; 2. As a diffuse pigmentation of greater or less intensity, which sooner or later becomes the seat of leukodermatous changes in the shape of small spots that gradually increase in size; this is the retiform pigmentary syphilide; 3. In an abnormal distribution of the pigment of the skin, in which, owing to the lack or crowding out of the pigment in places, areas become whiter, while the parts invaded in the abnormal distribution become darker. In this way a dappled appearance is presented. This form has been termed the marmoraceous form, from its resemblance to some forms of marble, in which there is an interblending of light and dark colors. It is not common, and is peculiarly liable, on account of its delicacy of tone and tint, to pass unobserved.

Dr. P. A. Morrow stated that he has observed a number of cases of pigmentary syphilide, which is recognized as a comparatively rare affection. Whether the leukoderma is primary or secondary has not been definitely settled. Many still claim that the essential process is an achroma. Dr. Morrow stated that he is inclined to accept the view of Dr. Taylor, namely, that the essential process is a hyperchroma, and that the white spots that form so characteristic and typical a feature are secondary.

Dr. J. A. Fordyce, of New York, stated that he has been on the lookout for a primary pigmentary syphilide for a long time, and he considers it an extremely rare affection. The second variety mentioned by Dr. Taylor is not so uncommon. Some writers claim that the loss and increase of pigment are coincident.

Dr. Taylor, in closing the discussion, stated that in the cases mentioned in his paper, of which he presented illustrations, he had watched the process from beginning to end. In some cases the whole brown expanse is formed before atrophy takes place; in other cases the atrophy does not occur at all.

Dr. John A. Fordyce, of New York, read a paper on "The Pathology of Syphilitic Nephritis." He related that at the last meeting of the Association he had briefly reported the history of a case of inflammation of the kidney, which had set in acutely in a previously healthy

man, thirty-four years old, four months after the appearance of the initial syphilitic lesion on the finger. The patient passed through a number of uremic accidents, and after the nephritis had existed for about three and one-half years the man died from uremic coma. An autopsy, made twelve hours after death, disclosed a general edema of the subcutaneous tissue. The kidneys were both below the average size; the capsules were somewhat adherent; their surfaces were granular. A small cyst containing about one dram of fluid was found beneath the capsule of the right kidney. On section, the organs were exceedingly firm. A mass of bluish-gray tissue that made up about one-half of the bulk of the right kidney, cut with difficulty, and seemed to be made up entirely of connective tissue. Upon microscopic examination, few normal Malpighian bodies were found. Many of them showed marked thickening of Bowman's capsule, and a homogeneous degeneration (probably hyaline) of the capillary vessels making up the glomerulus. A transverse section of the blood-vessels showed a marked thickening of their walls. The greater portion of the section was made up of a new-growth of connective tissue, the bulk of which was of comparatively recent formation; scattered throughout the section were numerous foci, showing that the interstitial process was in an active stage. While nothing absolutely pathognomonic of syphilis could be claimed, either for the clinical symptoms or the anatomic changes, Dr. Fordyce stated that he felt confident that the exciting cause of the malady was the specific infection, as careful search failed to elicit any other possible factor in its causation. In some cases of early syphilitic nephritis mercury has seemed to exert its specific effect on the kidney-lesions, and to bring about a speedy cure, while in others a fatal termination has taken place during or following the administration of the drug.

DR. R. W. TAYLOR stated that the subject of syphilitic nephritis is still in its infancy. It is known that late in the course of syphilis kidney-affections are occasionally found; then the question arises, whether the affection of the kidney is due to syphilis or to something else.

DR. P. A. MORROW stated that the occurrence of nephritis in the course of syphilis, whether as the result of the syphilitic infection or as an accidental inflammation, is more common than is generally supposed. His experience as to the effect of mercury on such a nephritis has proven very contradictory. In two or three cases the symptoms were apparently aggravated by the use of the drug; in other cases the results were most brilliant.

DR. E. L. KEYES, of New York, stated that he had seen a number of cases in which albuminuria appeared in early syphilis, and his impression is decided that the mercurial treatment is of advantage.

DR. TAYLOR stated that he is in the habit of examining the urine of syphilitic patients. Few cases present signs of kidney-involvement—perhaps from three to five per cent. They are usually amenable to properly directed mercurial treatment.

In closing the discussion DR. FORDYCE stated that the case reported by him would not respond to treatment by mercury given internally, by inunction, etc. In a number of cases on record, an existing nephritis seems to have been aggravated by the use of mercury.

DR. SAMUEL ALEXANDER, of New York, presented a communication entitled "Observations in Regard to the Pathology and Pathological Anatomy of Nodular or Granular Cystitis; Preliminary Paper."

The following conclusions were reached: The occurrence of nodules upon the mucous membrane of the bladder as the result of cystitis is not very uncommon; these nodules are frequently mistaken for tuberculous nodules; they consist of a very vascular lymphatic tissue, arranged in circumscribed foci resembling the follicles of the intestinal mucous membrane, but presenting more diffuse masses of cells; the occurrence of these nodules mparts a peculiar character to the clinical aspect of a cystitis, as manifested by pain, hemorrhage, protracted duration, and a great tendency to relapse; these lymph-nodules are simply the normal lymph-nodules of the bladder, enlarged. Nodular and tubercular cystitis may often coexist, but they are not to be regarded as the results of tuberculous infection.

DR. F. TILDEN BROWN, of New York, read a report of "Unusual Microscopic Bodies Found in the Secretions and Urinary Sediment of a Patient Suffering for Seventeen Years with Urethral Discharge." He related the history of a case in which a peculiar worm was found in the secretions and urinary sediment. The average length of the worm was about one millimeter, being much larger than the ordinary filaria sanguinis hominis; the largest one was about three millimeters in length. The parasite was very difficult to stain. The body was not segmented.

DR. E. L. KEYES, of New York, read a paper on "Relapsing Villous Papilloma of the Bladder." He reported a case in which a villous papilloma as large as a good-sized Mandarin orange, with a pedicle as large as an ordinary lead-pencil, was extracted from the bladder by a supra-pubic operation in November, 1886. In 1891 the symptoms returned, and a relapse of the papillomatous condition was clearly manifest. A second operation was performed in January, 1892. An incision was made above the pubis through the original scar, but the peritoneum was found to be so firmly bound down to the bladder that this avenue of approach was abandoned and a perineal opening made. Upon the site of the original villous growth was found a pedunculated villous tumor, which was removed with a sharp spoon.

DR. BRYSON narrated a case in which he removed a large villous growth from the wall of the bladder; the patient got well, but immediately after the operation he exhibited a good deal of mental disturbance, suffering from insomnia and delusions. These manifestations were ascribed to the use of the anesthetic; they finally subsided, and the man became perfectly well.

DR. KEYES stated that he also had a case in which the removal of a tumor from the bladder was followed by mental aberration.

DR. CABOT stated that in a case of villous growth of the bladder upon which he had operated, the patient, a physician, became very irritable, and acted strangely after the operation; he finally became insane and was committed to an asylum. Whether or not the operation had anything to do with the mental condition, however, was doubtful, as it was stated that the man had previously shown signs of mental weakness.

SECOND DAY—JUNE 22D.

The following officers were elected for the ensuing year: President, Dr. Edward R. Palmer, of Louisville, Ky.; Vice-President, Dr. L. Bolton Bangs, New York; Secretary, Dr. John A. Fordyce, of New York.

It was also decided to change the name of the Association to the American Association of Genito-Urinary Surgeons. The next meeting is to be held at Cumberland Gap, Tenn., in June, 1893.

The discussion on "Prostatectomy" was opened by a communication from DR. WILLIAM T. BELFIELD, of Chicago. From a study of 133 operations upon the enlarged prostate the following conclusions were arrived at: 1. In the majority of prostatics the failure to evacuate the bladder is due not to degeneration of the vesical muscles, but to the mechanical obstruction offered by the prostatic growth. 2. This obstruction is usually of such form as to be overcome by operative measures. 3. These measures should secure restoration of a low-level urethra by removal of the prostatic obstacles, thorough stretching of the prostatic urethra and temporary drainage of the bladder. 4. From the anatomic standpoint, suprapubic cystotomy is, in the abstract, with certain exceptions, preferable to perineal cystotomy. The perineal approach to the prostate, however, should be selected for feeble patients.

DR. JOHN P. BRYSON, of St. Louis, read a paper on "Prostato-Myomectomy by the Supra-pubic Route; with a Report of Results Obtained in Eleven Cases." He detailed the histories of eleven cases in which he had operated upon the prostate. He expressed the view that the more closely the symptoms of prostatic overgrowth resemble those of a foreign body or tumor in the bladder the stronger the reason is for operation.

DR. WILLIAM N. WISHARD, of Indianapolis, read a paper on "Perineal Prostatectomy." He stated that while the prime object of prostatectomy is the removal of mechanical obstructions to urination, an object of scarcely less immediate importance is bladder-rest and drainage. For the purposes of rest and drainage, it is generally conceded that the perineal incision is easily and generally safely performed; the benefit thus obtained is, in some instances, more or less permanent, particularly when stretching the prostatic urethra accompanies perineal incision. In some instances, the length of the prostatic urethra is so greatly increased that an effort to remove obstructing tissue by an opening through the membranous urethra is attended with great and often insurmountable obstacles. McGill states that inability to reach and explore the bladder by this route exists in about thirty per cent. of all cases. Dr. Wishard reported the clinical history of and presented the specimens from two cases of lateral enlargement of the prostate in which the gland was removed through a perineal opening.

DR. KEYES stated that for the profuse hemorrhage sometimes encountered in operations upon the prostate he has devised a gauze tampon, which is drawn into the wound by means of a string passed through the urethra. A string is also attached to a button fastened to the upper surface of the pad or tampon, by which this can be withdrawn through the supra-pubic opening.

DR. BANGS referred to the value of prolonged drainage in cases of operation for enlarged prostate. He inquired as to the death-rate following operations on the gland. He related that he had been able to control severe hemorrhage in the course of operation with an iodoform-gauze tampon pressed against the wound by means of a long hemostatic clamp or sponge-holder, kept in place by the abdominal dressing.

DR. KEYES stated that the death-rate following operations on the prostate is perhaps 25 per cent.; certainly not lower than 16 per cent. Prostatectomy should be considered an emergency-operation that should not be performed if it can possibly be avoided.

DR. F. TILDEN BROWN, of New York, read a paper on "The Pathology of Urinary Fever." He discussed and classified the various theories, both physiologic and pathologic, that have been advanced in connection with the disorder.

DR. JOHN P. BRYSON, of St. Louis, read a paper entitled "Influence of Asepsis and Antisepsis on the Prophylaxis of Urethral as Distinguished from Urinary Fever." He stated that there has been a progressive diminution in the frequency of urethral fever in his practice, notwithstanding an increased number of operations. This diminution in frequency is due to changes in the technique of urethral antisepsis. The plan pursued at present is as follows: 1. When possible, some one of the urinary antiseptics is given by the mouth from twenty-four to forty-eight hours before the operation. 2. All instruments are rendered aseptic by boiling in soda solution. 3. Boracic glycerin alone is used as a lubricant. 4. Before instrumentation the foreskin is retracted and the glans and prepuce are thoroughly washed with the boro-salicylic acid solution of Thiersch. 5. The anterior urethra is also filled with this solution, and is allowed to empty itself several times. 6. The posterior urethra is likewise washed with this solution, either by over-distending the anterior urethra, or, failing in this, by means of an Ultzmann's syringe.

DR. E. L. KEYES, of New York, read a paper entitled "Failure of Diuretin to Avert Urethral Fever." He revoked the conclusion announced a year previously that diuretin appeared to have the power of averting urinary or urethral fever. Despite the free administration of the drug, and the adoption of other precautions, urinary fever has appeared and run its course. Dr. Keyes stated that he knows of no positive, certain means of averting urinary fever in every case, and he relies upon a combination of salol and diuretin, with bichloride irrigation, and warmth and rest in bed.

DR. W. FRANK GLENN, of Nashville, Tenn., read a "Further Report on the Treatment of Gonorrhea." He stated that in connection with a previous report on the treatment of gonorrhea by means of injections of chloride and iodide of zinc, the point was made that as a microscopic examination had not been made in each case, and gonococci demonstrated, many or perhaps none of the cases were instances of specific gonorrhea, and therefore the treatment might not have been as successful as the report indicated. Dr. Glenn has since collected twenty-four cases, in all of which microscopic examination was made and gonococci demonstrated. The average length of time required for a cure was sixteen and $\frac{7}{24}$ days. This average would have been still further reduced but for the fact that two of the patients included in the list neglected themselves and had sexual intercourse during the time of treatment.

CORRESPONDENCE.

"FEBRICIDE."

To the Editor of THE MEDICAL NEWS,

SIR: Referring to my paper against the use by physicians of "patent medicines," read before the Philadelphia County Medical Society (THE MEDICAL NEWS, May 14, 1892, p. 556), the manufacturers of the compound called "Febricide," which I cited as among the nostrums advertised in the *Journal of the American Medical Association*, have called my attention to the fact that they had in former years published the composition of their pills in their advertisements, and have sent me copies of such advertisements. While this does not remove the weighty therapeutic objections that hold against all ready-made combinations, the prescription of which may be highly injurious in a particular case for which the ingredients and proportions have not been specifically adjusted, and while I take no blame to myself for not hunting up advertisements some years old, it does, of course, take the preparation out of the category of secret nostrums, and frees the manufacturers from the stigma attaching to the preparation of articles belonging in this category. As I have no desire to be unjust to anyone, I make this correction.

Yours truly,

S. SOLIS-COHEN, M.D.

219 SOUTH SEVENTEENTH STREET.

THE APOTHECARY'S OATH.

To the Editor of THE MEDICAL NEWS,

SIR: While reading Boas's *History of Medicine* I found the following oath, as taken by the apothecaries of the thirteenth century: "To honor, esteem, and serve the doctors of medicine, ... to speak no evil, ... and to do everything which may contribute to the honor, reputation, embellishment, and majesty of medicine."

Is there a nineteenth-century apothecary that would show his allegiance to and dependence upon the medical profession as did these men of old? Where has progress shown itself along this line? What cares the druggist for the doctor to-day when he has the quack to back him?

The contrast is startling. Look at a drug-store to-day. Where are the drugs? Their place is taken by nostrums, soda-water fountains, and bric-a-brac, and in a back part of the store there is a small sign bearing the legend "Prescriptions Compounded." Is this not a typical example of commercialism *versus* love of mankind?

I could not refrain from sending you this short communication, as it occurred to me soon after reading one of your editorials. Respectfully,

LEWIS S. SOMERS, M.D.

1622 PARK AVENUE.

MEDICAL PRACTICE IN NEW JERSEY.

To the Editor of THE MEDICAL NEWS,

SIR: There seems to be a widespread misapprehension as to the provisions of the new law regulating the practice of medicine in New Jersey. Many of my medical friends in Philadelphia have supposed that they could not come here temporarily to prescribe for their own patients, or even respond to a summons to see a case in this State in consultation, unless regularly registered as practitioners in New Jersey. One physician now here for his health imagined that he would not be permitted to write a prescription for himself. The following article of the Act shows that the restrictions are not quite so ironclad as is generally believed, though less liberal than they should be regarding physicians licensed to practise in other States who might desire to accompany their patients here and remain with them here during a part or all of a season:

"7. And be it enacted, That this Act shall not apply to commissioned surgeons of the United States Army, Navy, or Marine-Hospital Service, *or to regularly licensed physicians or surgeons in actual consultation from other States or Territories, or to regularly licensed physicians or surgeons actually called from other States or Territories to attend cases in this State*, or to any person now entitled to practise medicine in this State."

Very truly yours,

BOARDMAN REED, M.D.

ATLANTIC CITY, N. J.

NEWS ITEMS.

The Sanitary Conditions of Florida.—The following letter and certificate will be of interest to physicians who have patients intending visiting Florida health-resorts:

WASHINGTON, D. C., June 13, 1892.

A. ANDERSON, M.D.,
FRANK FREMONT-SMITH, M.D.,
Physicians to Hotels Ponce de Leon, Alcazar, and Cordova.

GENTLEMEN: In compliance with your request I give the following statement. As the result of a careful investigation of the sanitary condition of the Hotels Ponce de Leon, Alcazar, and Cordova, in St. Augustine, Fla., and of such accounts of the cases of fever which occurred in guests of these hotels during the spring of 1892, as it has thus far been possible to obtain, I am satisfied that no one of these cases of fever was caused by the water-supply, or by the drainage of the buildings, or by anything connected with them or their surroundings. The water-supply has been examined chemically and bacteriologically, the plumbing and house-drainage of each hotel have been carefully scrutinized, the sources of milk-supply, of ice, and of fresh vegetables for the use of the guests of these hotels have been investigated, and no causes of disease have been found in any of them. There have been no cases of typhoid fever among the residents in St. Augustine during the past year, and the general sanitary condition of the town is excellent.

Between December 15, 1891, and April 25, 1892, about twenty-five cases of typhoid fever are reported as having occurred in about 25,000 persons who visited St. Augustine. Fourteen of these cases occurred among visitors while they were in the town, and eleven are said to have occurred from two to three weeks after the patients had left the town. In addition to the above, four cases are reported in hotel servants and one in a nurse. Seven of the cases in visitors while in the town were in the Hotels Ponce de Leon, Alcazar, and Cordova, and six of the cases reported in persons who had

been gone from two to three weeks, were also in guests of these three hotels. In all, therefore, out of about 16,000 guests of these hotels, thirteen are reported as having been affected with typhoid. The investigation into the details of these cases is not yet completed, and I can only say now, that it is probable that two or three of them were not typhoid fever at all; that two of them were ill on the day of their arrival, which illness became well-marked typhoid five days later, and, therefore, was not contracted at St. Augustine; and that of all the cases at the above-mentioned hotels there were among the guests but three which it would seem must have been contracted during their stay in St. Augustine. The four servants affected with typhoid probably had the specific cause introduced into their bodies through contact with a fever case, or cases, or with soiled linen from such case.

Every educated physician will understand from the above figures the extreme improbability that so few cases, scattered over a period of two months and giving a ratio of less than one to a thousand people exposed, could have been due to anything in the structure of the buildings, the general water-supply, or the food, milk, or ice—and the detailed investigation of all these things makes it practically certain that no case of typhoid was due to any of them.

Whether the investigation, now in progress, into the history of the reported cases will indicate the source of the disease is, of course, doubtful, and probably the cases had no common source, but were each contracted at a different time and in a different place; but knowing, as I do, the great interest in these Southern winter health-resorts felt by a large number of Northern invalids, it has seemed best to make this preliminary statement in order to assure them that they can make their plans for going to St. Augustine next winter with perfect confidence; that, while absolute security can be had nowhere, so long as they are there they will probably be less liable to be exposed to the contagion of typhoid fever than they will be if they remain at home.

[Signed] JOHN S. BILLINGS, M.D.,
Surgeon U. S. A.

BOARD OF HEALTH OF ST. JOHN'S COUNTY.

ST. AUGUSTINE, FLA., June 10, 1892.

We, the Board of Health of St. John's County, Florida, do hereby certify that, prior to the month of April, A. D. 1892, there were no deaths reported to this Board resulting from fever of any kind, nor does this Board have any knowledge of the existence of any case of fever in the city of St. Augustine, or St. John's County, prior to the period above mentioned; that during the month of April, A. D. 1892, the following deaths from fever were reported to this Board:

1. Florence Hawley Glover Clark, white female, aged thirty-seven years; residence, Newton, Conn.; died April 3, 1892; cause of death, typho-malarial fever; reported by F. Fremont-Smith, M.D., attending physician.

2. Elizabeth M. Park, white female, aged thirty-five years; residence, Rye, New York; died April 5, 1892; cause of death, typho-malarial fever; reported by F. Fremont-Smith, M.D., attending physician.

3. Joseph N. Knight, white male, aged thirty-four years; residence, Highwood, New Jersey; died April 14, 1892; cause of death, typho-malarial fever; reported by F. Fremont-Smith, M.D., attending physician.

4. Irene L. Davis, white female, aged twenty-six years; residence, Philadelphia, Pa., died April 17, 1892; cause of death, typhoid fever; reported by F. Fremont-Smith, M.D., attending physician.

That all of said deaths occurred in the city of St. Augustine; and that since the 17th day of April, 1892, there has been no report to this Board of death from fever of any kind.

We further certify that the rules of this Board require attending physicians to report deaths to this Board within twenty-four hours after the same occur; and that all deaths are so reported by the physicians of this county in whose practice a death may occur; that at the present time we have no knowledge of the existence of any case of fever in the city of St. Augustine, or the county of St. John's, but the certificate of practising physicians in this city and county is, in our opinion, the best evidence as to whether or not fever of any kind exists here at the present time.

We further certify that the sanitary condition and healthfulness of this city and county are very good and have never been better.

WILLIAM F. SHINE, M.D.,
President St. John's County Board of Health.
T. E. B. KERNAN.
A. J. CORBETT,
Secretary.

Dr. James S. Green, President of the New Jersey State Medical Society, died at Elizabeth on July 2.

Fischel, a distinguished psychiatrist, died at Prague, on June 4, at the age of seventy-nine.

PULMONARY PHTHISIS IN ITS RELATION TO INSANITY AND TO OTHER NEUROSES.[1]

BY THOMAS J. MAYS, M.D

PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND VISITING PHYSICIAN TO THE RUSH HOSPITAL FOR CONSUMPTION, OF PHILADELPHIA.

DURING recent years I have been devoting a good deal of attention to the study of the nervous nature of pulmonary phthisis, and have latterly given expression to my views on this subject in a brochure entitled *Pulmonary Consumption a Nervous Disease*. In this publication I said all that I deemed necessary to say at that time. Continued research in the same field has, however, not only served to confirm my previous opinion, but shows that a more intimate relation exists between pulmonary phthisis and the ordinary neuroses than I then conceived, so that I have for some time been thinking of gathering the evidence of this relationship for further publication. This I would hardly have undertaken so soon if, in the meantime, there had not appeared a book which, on account of its broad generalizations and scientific deductions, stamp it, in my opinion, as one of the most philosophic works that has been issued from the medical press for a long while. This work is Dr. Clouston's book on *The Neuroses of Development*, and to it must be chiefly ascribed, not only the inspiration and incentive of what I shall say to-day, but also much of the matter that makes up the body of this paper.

The clinical association between mental diseases and phthisis has been noticed by many authors, among whom are Van der Kolk, Esquirol, Georget, Burrows, Ellis, McKinnon, Clouston, Boyd, Savage, Norman, and others. The illustrious Laennec, who himself fell a victim to phthisis, says (*Treatise on Mediate Auscultation*, Paris, 1822) that he knew of no more certain cause of this disease than profound or prolonged grief or melancholy. From various sources we learn that phthisis is about three times as prevalent among the insane as among the sane, the mortality among the former being estimated at 20 per cent. By some this high death-rate is attributed to the confinement incidental to asylum-life, but this relation is, after all, more apparent than real, for Boyd (*Journal of Mental Science*, vol. xv, p. 196) shows that out of 147 insane that died of phthisis in the Somerset Asylum, there was a slight increase (4.7 per cent.) in the death-rate of the females that were longest confined; while, on the other hand, there was a slight decrease in the death-rate (3.6 per cent.) of the male inmates that were longest confined.

All observers, so far as I am aware, are agreed in the opinion, too, that the insanity is a precursor of the phthisical affection among the insane. This explains why, as Clouston remarks, insanity is not more frequently found in hospitals for pulmonary consumption.

Not only is phthisis more common among the insane than it is among the general population, but facts show that this disease has a predilection for certain forms of insanity. Thus, it is more likely to occur in the depressed than in the exalted types of insanity. Clouston says that this is especially true of melancholia, when combined with the monomania of suspicion, and that sooner or later nearly all these cases die of pulmonary phthisis. Riva and Sulphide (*London Medical Record*, 1879, p. 479) also state that phthisis is more common in melancholia than in any other form of insanity; but it is also found in general paralysis, or paretic dementia, for Sir J. Crichton Browne (*Brain*, vol. vi, p. 317) states that phthisis existed in 25 per cent. of cases of general paralysis examined after death. My own observation leads me to believe that general paralysis, or paretic dementia, is not infrequently associated with phthisis. This opinion is based on an analysis of the statistics of the Department of the Insane in the Philadelphia Hospital, which was made with the assistance of my friend, Dr. Charles Wirgman.

The Ages of Greatest Prevalence of Pulmonary Phthisis and Insanity.—The most superficial examination of mortality statistics makes it clear that the human constitution is more vulnerable to phthisis at certain periods of life than at others, although it is true that those who inherit the disease die three years earlier than those who acquire it. This is true, whether the disease affects the lungs, the brain, the bones, or any other portion of the body. Thus, in 17,711 cases of phthisis collected from the Health Reports of the City of Philadelphia and of Rhode Island, I find that the greatest mortality among these prevailed between the ages of twenty and thirty. In regard to tuberculous

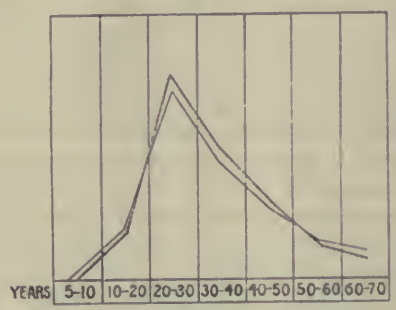
[1] Read before the meeting of the American Neurological Association, New York, June 24, 1892.

meningitis, Dr. James shows (*Pulmonary Phthisis*, p. 4) that the percentage of deaths from this disease is the heaviest in the twelfth month of infancy, and sinks to a minimum after the third year.

Turning now to an inquiry into the morbidity-rate of insanity, we find that this condition not only pursues a similar course in regard to periodicity, but that this periodicity corresponds precisely with that of pulmonary phthisis. Thus, James (*Ibid.*, p. 41) shows by a curve based on 3985 inmates of the Morningdale Lunatic Asylum of Scotland, that the greatest number of lunacy cases develop between the ages of twenty-five and thirty-five. The *Report of the Pennsylvania Hospital for the Insane*, for the year 1888, gives the ages at which insanity first appeared in 9543 patients, and showing the greatest prevalence of insanity to be between twenty and thirty years.

I have constructed a chart, showing the prevalence of phthisis and insanity at various life periods, in the total number of cases reported in the statistics quoted, and from this a comparative view of the course of the two diseases is readily obtained:

FIG. 1.



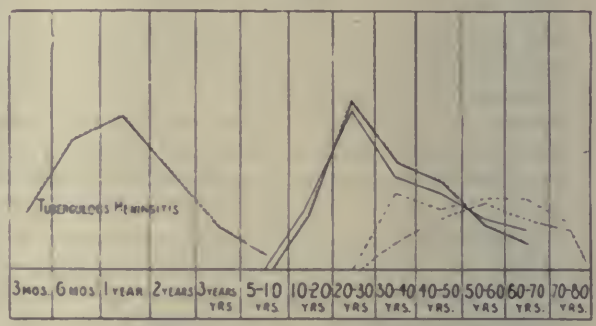
The comparative courses of pulmonary phthisis and insanity at various stages. The dotted line represents the curve of pulmonary phthisis or consumption, and the solid line that of insanity. The cases of pulmonary consumption on which the dotted line is based, numbering 17,711, are derived from the sources indicated. The cases of insanity on which the solid line is based, numbering 9543, are obtained from the *Report of the Pennsylvania Hospital for the Insane*, for 1888.

A most interesting feature is brought out in this connection, if the various ages at which tuberculous meningitis mostly flourishes are contrasted in a graphic manner with those at which pulmonary tuberculosis and insanity are most prevalent, as will appear from the accompanying representation.

From this it will be seen that tuberculous meningitis affects early infancy almost exclusively; that pulmonary consumption and insanity occur at a time when tuberculous meningitis ceases to occur, and pursue a parallel course throughout their continuance. The significance of these curves will receive interpretation when the influence of development in the etiology of disease is considered.

The Influence of Heredity in the Causation of Pulmonary Consumption and Insanity.—That the neurotic tendency breeds pulmonary consumption in the offspring has been recognized since the days of Moreau. Hysteria, chorea, epilepsy, etc., are often intermingled with pulmonary consumption in different generations of the same family. The same is true concerning insanity. Clouston (*Neuroses of Development*, p. 91) tells us that pulmonary consumption and insanity are common in different members of the same family, and a tuberculous heredity may determine insanity, and *vice versâ*.

FIG. 2.



Dr. James, in referring to the subject of heredity, states (*Pulmonary Phthisis*, p. 109) that "If we compare phthisis with diseased conditions which all observations show are quite independent of micro-organisms, as insanity, very close resemblances are found." He, furthermore, says that Thompson has demonstrated the truth of this (*Family Phthisis*, p. 132) by comparing smallpox and syphilis with insanity and phthisis as follows:

	Smallpox.	Syphilis.	Insanity.	Phthisis.
Transmission.	Through mother only.	Through either parent.	Through either parent.	Through either parent.
Time of appearance.	Closely on disease in mother	Closely on disease in parents	Not always closely on disease in parents	Not always closely on disease in parents
Protective or not	Is protective.	Is protective.	Is not protective, but predisposing.	Is not protective, but predisposing.
Atavism	Unknown.	Unknown.	Rather frequent.	Rather frequent.
Ultimate effects.	Extinction of the disease.	Extinction of the disease.	Extinction of the family.	Extinction of the family.

Commenting on these phenomena, Dr. James declares that "here the resemblance between phthisis and insanity is as complete as is their distinction from smallpox and syphilis, and this comparison indicates that whilst such diseases as smallpox and syphilis must be looked upon as being the results of

some foreign growths implanted in the body, as in a soil, and there passing through the various stages of their life-history, insanity and phthisis may be regarded rather as being the results of some peculiar modification of the body itself, the nature of which we do not understand, but which we vaguely term deficient vitality."

Asthma and Pulmonary Phthisis. — Although asthma is a well-recognized disease, its life-history has not been investigated with the thoroughness that its importance demands. This is particularly true with regard to the tendency through which it produces death. The question then is, Of what do asthmatics die? Do they die of asthma, or of some other disease, and if so, what is the relation between the asthma and the disease of which they die? Asthmatics are supposed to be long-lived, but of this I cannot find any corroborative evidence, either in the experience of others or in that of myself. I do not refer to those exceptional cases that undergo spontaneous cure in the later years of life, but to those in whom the attacks incline to become continuous as life advances. Text-books on the practice of medicine, and even most of the special treatises on this subject give no satisfactory answer, but evidence can be gathered to show that asthma naturally develops into pulmonary consumption. Fuller (*Diseases of the Chest*, 1862) states that, in spite of the belief that asthma and pulmonary consumption are antagonistic, many asthmatic patients die of the latter disease. Williams (*Pulmonary Consumption*, 1887, p. 317), in tracing the origin of 385 cases of pulmonary consumption, shows that seven began with spasmodic asthma. On page 61 of the same work he says that the tendency of asthmatic parents to have tuberculous children is hardly sufficiently recognized. James (*Pulmonary Phthisis*, p. 57) asserts that asthma and whooping-cough are likely to predispose to or terminate in pulmonary phthisis. In my own experience I have seen four cases of asthma that developed into pulmonary consumption, and of these two died. It appears that the danger of asthma lapsing into pulmonary consumption only begins when the attacks of the former follow in such close succession that the irritation produced by the preceding paroxysm has not had time to subside; this is not the case when the attacks recur after long periods of intermission. It seems, therefore, that it is more or less an accumulation of the effects of asthma that develop the phthisical state, the danger of which is averted when sufficient time elapses between the attacks for these morbid effects to pass off.

These facts tend to demonstrate, then, that asthma is closely associated with consumption on the one hand, and I think the instances that follow will make it clear, too, on the other hand, that asthma is closely related to insanity. Clouston (*Neuroses of Development*, p. 65), after defining asthma as a neurosis of the pneumogastric center, says that it often disappears, and is superseded by other nervous diseases, and that its alternation with mania, chorea, and hysteria, is quite common. On looking up the subject of the alternation between asthma and insanity, I have found a number of additional cases to those related by Dr. Clouston in his various writings, and, on account of their great interest, I shall present a short abstract of them.

CASE I.—(Kelp, *Zeitschrift f. Psych.*, xxix, 4.) M., a male, twenty-eight years old, with a family history of insanity on both sides, became asthmatic at twenty-one; he took large doses of morphine and chloral. After some time the asthma disappeared entirely, and was superseded by mania. He presented extreme depression and anxiety, amounting to desperation, accompanied by a delusion that he was being poisoned. After a time the asthma reappeared, and the mental condition gradually improved.

CASE II.—(Dr. Lorent, *Ibid.*) A male adult, who had long suffered from asthma, fell ill of melancholia, when his chest-troubles vanished. Nine months afterward he recovered from the mental affection, and the asthma returned. A year after this the chest-troubles disappeared again, and the melancholia recurred.

CASE III.—(Dr. H. B. Nunemaker; private communication.) A male, fifty-five years old, presented paroxysmal mania for about four weeks, when attacks of spasmodic asthma came on, and displaced the mania. These alternations occurred once in about eighteen months, and took place three times while the patient was under observation.

CASE IV.—(Dr. J. C. Stevens; private communication.) An intemperate male adult was asthmatic for ten years, after which he became insane. He had various delusions, and was subject to paroxysms of abuse and excitement. Occasionally, in the midst of these, an attack of asthma, lasting for a few days, would come on. At these times he was apparently sane. After the asthma disappeared, the mania returned. Finally, the asthma became more or less constant, and the patient remained sane.

CASE V.—(Conolly Norman, *Journal of Mental Science*, vol. xxxi, p. 1.) A female, forty-five years old, suffered from asthma for twenty years. Three months before she came under observation her asthma ceased suddenly, and she became restless, anxious, and melancholic. In two and a half years her asthma returned, but her mental condition did not improve.

CASE VI.—(*Ibid.*) A male, thirty-two years old, had asthma from childhood. The asthma ceased, and he became gloomy, irritable, and was haunted by the thought that he was to kill his mother. A fortnight after admission to hospital he had an attack of asthma. He at once improved. He became cheerful, the asthma recurred frequently, but his mental condition remained undisturbed.

CASE VII.—(*Ibid.*) A male, about twenty years old, had asthma for some time before he became insane. After being confined in an asylum for three years he became perfectly calm, and the asthma returned; from this he suffered for years. The asthma was not observed when he was maniacal.

CASE VIII.—(*Ibid.*) A female, at the age of thirty, became asthmatic, and suffered until she was about forty, when, on account of some financial distress, she became insane—suffering from delusions of suspicion. After about six months' seclusion, her mind cleared up. During this time she had no asthma. Her asthma returned, but so far as known she had no recurrence of insanity.

CASE IX.—(*Ibid.*) A male, thirty years old, had been a sufferer from asthma for many years. Two years before admission to hospital the asthma became less severe, and his friends date his insanity from that time. After being confined for a year or more, his mind gradually cleared up, and the asthma returned in a severe form. The chronic, calm condition of partial dementia was well established before the onset of the asthma, and the mind remained unchanged.

CASE X.—(Clouston, *Neuroses of Development*, p. 122.) A female became asthmatic at thirteen years of age. At thirty-seven she became melancholic, with delusions, and the asthma ceased.

CASE XI.—(*Ibid.*, p. 24.) A boy, one year old, had an attack of infantile paralysis, followed by impairment of growth of the bones and muscles, with weakness and contracture of the right arm, and lameness of the right leg. At puberty he became asthmatic; at nineteen the asthma ceased, and he had a severe attack of melancholia, attended with excitement. This lasted for six months, before and during which time he became thin and anemic. As the melancholia passed off the nutrition improved, and the asthma returned.

Commenting on this case, Dr. Clouston says: "What was the significance of the asthma—a spasmodic explosive condition, probably, of the pneumogastric centers—coming on at puberty, and of the excited melancholia at nineteen? Why were the lower and nutritive centers affected first, during the most active period of growth?—and then the respiratory centers?—and then, in order, the mental centers during the reproductive and higher mental development? And why did the asthma cease when the melancholic attack came on? Why was there a failure in the nutritive power of the whole body, as seen by the loss in weight and want of appetite before the melancholia began? Why did he recover from the melancholia instead of passing into dementia, as so many cases of adolescent insanity do? Why did the asthma return? Did its return save him from dementia?"

Although the phenomenon is less frequent and less pronounced, yet there is evidence to show that it is possible for a similar interchange, or at least a transmutation, to occur between insanity and phthisis as there is between insanity and asthma, as is attested by the following short histories:

CASE I.—(Dr. Ray, *American Journal of Insanity*, 1862, vol. xix, p. 40.) A female presented symptoms of pulmonary disease, and soon after cerebral symptoms. She became so excited that she was sent to an asylum. The excitement abated under treatment, and she went home as rational as ever, but the pulmonary disease returned, and she subsequently died of pulmonary phthisis.

CASE II.—*Schmidt's Jahrbücher*, suppl., 1847, p. 72.) A male, twenty-five years old, made a slow recovery from pneumonia. In the following year all objective signs of the pulmonary disease had disappeared. He then became melancholic, and his head was turned spasmodically to the right. He finally died with dyspnea and dysphagia. On examination his brain was found congested and edematous, and there was a cavity in the apex of the right lung.

CASE III.—(Dr. Edward N. Brush; private communication.) A female, twenty-one years old, became melancholic, and received asylum treatment for nine months. During this time she improved, and became perfectly rational during the last three months of her hospital-residence. There was now observed an evening rise of temperature, and an infiltration at the apices of the lungs. She rapidly sank from consumption, but there was no recurrence of melancholia.

CASE IV.—(*British and Foreign Med.-Chirurg. Review*, lix, 59, p. 117.) Dr. Vosin relates the case of a female who, after suffering from melancholia, with stupor, for four years, was attacked with pulmonary consumption but recovered from her insanity.

These cases give still further proof of the close alliance between insanity and pulmonary phthisis.

Idiocy and Phthisis.—Of all the nervous diseases none is more frequently associated with pulmonary phthisis than idiocy. Indeed, this intimacy is so strongly maintained that one is tempted to be skeptical until the statistics on the subject are fully examined. Thus, Dr. Langdon Down, physician to the Earlswood Asylum for Idiots, says (*Mental Affections of Childhood and Youth*, p. 221), that "the statistics of London show that the deaths from phthisis constitute 115 per 1000 of the general mortality. My notes of the causes of death at Earlswood indicate that phthisis was the actual cause of death in 398 per 1000 of the general mortality. . . . . I have made an analysis of the last hundred of my post-mortem records, and I find that no fewer than 62 per cent. were subjects of tubercular deposit. . . . In several of the cases included in the above record, most careful inquiry failed to discover any family history of tuberculosis. . . . In these cases the tuberculosis appears to have been the sequence of idiocy. . . . Defective innervation, in all probability, led to mal-

nutrition, and predisposed to a tubercular condition. . . . On the other hand, in a large number of cases the progenitors had also manifested a tubercular condition; and in some the tuberculosis of the parents had been, in my opinion, the prime cause of the idiocy of the offspring."

Dr. Isaac N. Kerlin, Superintendent of the Pennsylvania Institution for Feeble-minded Children, in an essay on the Classification and Causation of Idiocy (*Transactions of the Pennsylvania State Medical Society*, 1889, vol. xiii, part i, p. 161), states that "the tables presented with this paper, if prepared by a special advocate to prove that consumption is the main factor in the generation of idiocy, could not be more startling. As they are the result of careful inquiry, without any theory to prove or disprove, I ask for them your respectful judgment in this, as in other details which they present."

In the table to which he refers he gives the histories of 100 families, in each of which there was a case of idiocy. A careful examination of this table shows that 145 members of these families, including parents, sisters, and brothers, and grandparents, were afflicted with pulmonary consumption, 25 with insanity, and 21 with epilepsy. Dr. Down (*op. cit.*, p. 190) contributes the histories of 20 families, each of which was burdened with idiocy, and among the parents, sisters and brothers, grandparents, uncles and aunts, there were 35 who suffered from pulmonary consumption, 10 from insanity, and 3 from epilepsy. The great prevalence of pulmonary consumption among families that contain idiots is, however, no more startling than is its prevalence where hysteria exists. Thus, Professor Grasset (*Brain*, vols. vi and vii) found that among the parents, brothers and sisters, grandparents, and uncles and aunts, of 44 hysterical patients, there were 60 that were phthisical, 5 insane, and 2 epileptic. In order to grasp the enormous mortality from pulmonary phthisis among the members of families burdened with these neuroses, let us compare their death-rate with that which obtains among the members of families believed to be in good health, with no special predisposition to nervous disorders. Thus, if we take in order 1000 applicants for life-insurance (all not insured, for a number of these were rejected) as they are entered on the record-book in a life-insurance office, as I have done, we shall find that among the members of their families only 176 were consumptive, 9 insane, and 4 epileptic. By tabulating these figures in percentages, *i. e.*, by obtaining the proportion between the members of each hundred families represented and the number of sufferers from pulmonary consumption, insanity, and epilepsy, the contrast between the normal and the abnormal will be brought out in a most striking manner.

A comparison of these figures demonstrates that the death-rate from pulmonary tuberculosis is from eight to ten times as great among families of the neurotic class as it is among those of the healthy population. Not only is this an enormous death-rate, but, from further inquiry, it appears that, at least among the idiotic class, pulmonary consumption occurs earlier in life than it does among the general population or among the insane. Thus, it has been demonstrated that the greatest general mortality of consumption takes place between the ages of twenty and thirty; but in Dr. Down's record of 80 idiots that died of phthisis, the highest mortality-period is between ten and twenty years, showing that congenital or infantile disease of the brain and nervous system is capable of causing the greatest mortality-period of pulmonary consumption to appear ten years earlier than it otherwise would.

[1] As already defined.

In concluding this interesting chapter on idiocy, Dr. Down states: "It appears to me that tuberculosis must be accepted as one important cause of idiocy; that it impresses special characters thereon which impart a strong family likeness to the subjects of this class. It is no less clear to me that idiocy of a non-tubercular origin leads to tuberculosis. Whether this arises through the influence of the pneumogastric nerve, mal-assimilation of food, or defective innervation, it cannot but be regarded that the connection between these two maladies is by no means accidental, and that a due appreciation of this relation is necessary to those who would treat effectively congenital mental lesions."

Now, what interpretation can be given to these facts? Only one, so far as I can see, viz., that pulmonary phthisis and insanity belong to the same family-group of diseases. In order to comprehend this statement in its fullest extent, it must be borne in mind that that period in the life of an organ during which it undergoes development, either in structure or in function, marks a crisis in its history, and is the time when it is especially susceptible to disease. This point is particularly insisted on by Dr. Clouston, and it is in perfect accord with physiologic law. He holds that all true cases of epilepsy

arise almost exclusively during the growth and development of the brain. The first period is that of the most rapid brain-growth—from birth to seven years of age—and the second is that of slow brain-growth, but rapid development, the early reproductive period, from thirteen to eighteen years of age. In the great majority of instances chorea occurs between the ages of six and fifteen, the period of life when motion and emotion become coördinated. Megrim is a sensory neurosis that almost never appears before seven, or later than twenty five years of age. According to James, tuberculous meningitis is comparatively infrequent during the first months of life, reaches its maximum about the end of the first year, and then declines rapidly; the maximum, in all probability, corresponds with the time when the trophic and organic functions of the brain are most actively evolved.

The greatest prevalence of insanity—which is between twenty and thirty years—does not correspond with the maximum development of the structure of the brain, for this, as has been stated, takes place before the age of seven, and practically ceases at the age of twenty-five. It does tally, however, with that period in life at which the brain and nervous system undergo the most varied, intense, and complex development in function; for between twenty and thirty a new vista is opened to man. It is the period in which he is compelled to face untried and unsolved problems. He is removed from paternal protection, and left to struggle for his own existence in the battle of life. He becomes burdened with family cares and duties. He is exposed to overwork, business vicissitudes, mental anxiety and perplexities, domestic troubles, grief, disappointment, vicious habits, indulgences, intemperance, syphilis, and many other pernicious influences—influences that, by operating on a brain of either inherited or acquired instability, are known to be among the most prolific causes of insanity.

Pulmonary consumption, on superficial inspection, has apparently nothing, in a pathologic sense, in common with insanity, but on deeper examination the former proves to be a perfect analogue of the latter. Phthisis manifests itself during the developmental, and not, like carcinoma and chronic nephritis, during the degenerative period of life, and causes one-seventh of all of the deaths among the human race. It has been shown that the other diseases that arise during the corresponding period do so by reason of some structural or functional change in the organs affected, as a result of which susceptibility of these organs to disease is increased. Is this true of the lungs, in so far as they stand related to phthisis? Clouston is inclined to the opinion that there is present a trophic disturbance of development of the alveolar epithelium at the age at which phthisis is common, as a result of which a nidus is created for the lodgment and propagation of the tubercle-bacillus. With deference to this high authority, I am constrained to differ with him on this point. It is well known that the alveolar epithelium appears to be of a hybrid character, that it is most unstable, and has a much greater inherent susceptibility to disease during infancy than during any subsequent period; but so far as I am able to discern, there is no histologic or physiologic evidence to show that any development occurs in this structure at the time when pulmonary phthisis predominates; nor is there any proof that the lungs, as a whole, undergo growth in any respect during adult life. There being no such changes detectable in the respiratory organs, or in any of their component tissues, excepting in their nerve-supply, it becomes pertinent to inquire whether pulmonary phthisis is not primarily due to nerve-degeneration, and whether there is proof to substantiate this proposition.

Notwithstanding the great advance in the modern study of the neuroses, the pathologic relationship between the lungs and their nerve-supply has been practically ignored. The lungs are innervated by the largest and most important nerves in the body; yet, strange to say, nearly all of the diseases incidental to these organs are at present attributed to the influence of irritants and excitants introduced from without, and the possibility that the fault may reside in this nerve does not even receive serious consideration. It is not so in disease of other organs. When, for example, an arm or a leg refuses to perform its function, or fails in its nutrition, immediate inquiry is directed to the state of its nerve-supply. In disease of the eye, the condition of the optic nerve is carefully investigated. Inflammation and ulceration of the skin and subjacent tissues are known to be frequently due to disease of, or injury to, the nerves that supply these parts. A multitude of other instances might be given to illustrate the close dependence of the diseases of many organs on lesions of the nervous system.

Experiments, almost without number, demonstrate that section of, or injury to, the pneumogastric nerves of animals, is followed by degeneration of the lungs, as manifested by edema, hyperemia, splenization, hemorrhages, and emphysema—in fact, all of the elements of catarrhal or cheesy pneumonia. Professor Schiff, who has been largely interested in this subject, succeeded in developing both hepatization and tuberculization in the lungs of rabbits by irritating and injuring the pneumogastric nerves. In a series of experiments with rabbits, by wrapping the pneumogastric nerve of one side in cotton-wool saturated with glycerin, replacing it, and stitching the edges of the wound

together, I found that hepatization developed in every case, associated in one instance with yellow tuberculization.

It is true that this condition is known as "Schluck" pneumonia, implying that it is brought about by the entrance of mucus and particles of food into the trachea and bronchi of animals, in consequence of the paralysis of the pharynx and larynx produced by the operation. This view does not, however, seem to be correct, for Arusperger (*Virchow's Archiv*, vol. ix, pp. 197 and 437) has shown that if, after section of the nerves, a tube is inserted in the trachea, and the admission of foreign bodies into the lungs is prevented, the same pulmonary changes occur.

It is not necessary, however, to appeal to experiments on animals alone, in order to demonstrate that lesions of the pneumogastrics are capable of producing lung-disintegration, for there are many instances recorded in which pulmonary consumption in the human subject resulted clearly from disease of these nerves. In my brochure, already referred to, I submit the histories of eighty-one cases of pulmonary consumption associated with demonstrated disease of the vagus. In every instance these nerves were either compressed by aneurisms, enlarged glands, tumors, etc., or interfered with by other causes; and while it is hard to establish the fact that the lung-disease followed the nerve-lesion in every instance, this was undoubtedly the sequence in the vast majority of cases. In discussing the anatomic aspects of two of the cases included in my list, the late Sir William Gull referred to this very subject in the following language: "These cases afford an excellent illustration of the effects which are referable to paralysis of the pulmonary plexus on one side, accumulation of muco-purulent secretion in the paralyzed bronchi, subsequent dilatation of the tubes at their peripheral distribution, concomitant exudation into the air-cells, hepatization, and at length disintegration of tissue on the other. . . . It is one of the evils of a too exclusively humoral pathology (1859) that leads us to overlook the minute anatomical relations of disease, which are in themselves often a key to the sequence of morbid changes. These cases illustrate this proposition, for the possible local effects on the lung of injury to the pneumogastric and pulmonary plexus being recognized, whenever cause for that injury exists we may anticipate its results, and are not wholly dependent upon physical examination, as we are if we limit our pathological view to the mere changes in the lung, without considering how they are produced."

In making comments on one of his cases, to which I also refer in my list, Dr. Wilks, of London, expresses himself in a similar strain when he says: "It has been said that the patient died of phthisis, and the tumors were found accidentally; but, in all probability, the affection of the nerves—that is, of the pneumogastric—was the cause of the pulmonary disease, and, therefore, so far from neuroma being a harmless affection, it was the cause of the girl's death. This idea was suggested by the observation of several other cases of lung disease occurring in connection with disease of these nerves, particularly as witnessed in aneurism of the aorta and cancer of the esophagus. In these diseases death is often brought about by the pulmonary affection, and the pneumogastric nerves are found implicated in the disease, or pressed on by the tumor."

A brief analysis of my recorded cases develops the fact that twenty-nine show, as clearly as anything can be shown, that the phthisical degeneration was the result of a primary local disorganization of the vagi, due to the pressure of aneurisms, tumors, enlarged glands, etc., on these nerves. Here we possess all the requirements and conditions of a perfect experiment, such as we aim to secure in animals; and, unless we assume that pulmonary consumption preceded the local pressure on the vagi—a view that is not confirmed by anything that appears in the histories of the cases — we are bound to accept the proposition that phthisis is a direct sequence of disease of the vagus. In twenty other cases disease of the vagus and pulmonary phthisis were associated with various nervous affections, such as multiple neuritis, tabes dorsalis, bulbar paralysis, etc., and in each of these there is every reason to believe that the pulmonary lesions were secondary to disintegration of the vagi. In eighteen others it is shown that pulmonary consumption was the result of disease of the vagus engendered by the pernicious influence of alcohol and syphilis. In fourteen other cases pulmonary consumption and disease of the vagus were associated with diabetes and epilepsy. In my brochure I also tabulate the histories of sixty cases in which pneumonia, bronchitis, etc., coëxisted with well-ascertained disease of the vagi. Moreover, Drs. Bianchi and Armandi (*Neurolog. Centralblatt*, 1884, p. 452) found the vagi diseased in eleven paralytics that had died of pneumonia; and Dr. Bianchi, in a more recent contribution to this subject (*Neurolog. Centralblatt*, 1890, p. 249), states that in a number of paralytics, that had died of pneumonia, he was able to trace a primary degenerative atrophy of the vagi, and hence he believes that these pneumonias are dependent on degeneration of the vagus. He does not believe that they are induced by the swallowing of particles of food (*Schluck pneumonie*).

Here, then, is a record of 152 cases, in most of which disease of the vagus preceded pulmonary phthisis, or some other form of pulmonary dis-

ease. It may be urged, however, that in view of the general or local disease of the nervous system that coëxisted in these cases, there was reason to anticipate a lesion of the vagus, and the question may arise whether, in the ordinary form of pulmonary phthisis, not associated with any overt disease of the nervous system, a similar condition is found in the vagus. It seems to me, however, that this objection is more apparent than real, because all that the nervous origin of pulmonary phthisis demands is a showing that disease of the vagus is capable of engendering consumption regardless of whether this takes place in connection with well-recognized general nervous disease or not —I say with well-recognized nervous disease, for I am fully convinced that the majority of phthisical patients, if closely observed, would be seen to manifest well-defined symptoms of nervous disease. This opinion is substantiated by the pathologic research of Dr. Jappa (*Neurolog. Centralblatt*, 1888, Bd. vii, p. 425), who examined the peripheral nerves in the bodies of fifteen persons dead of pulmonary phthisis, and found marked degeneration in every case. He states that in these patients there were no nervous symptoms during life, except such as are found in almost all cases of the kind, as undefined muscle-pains, neuralgia, hyperesthesia, etc. Aside from all this, however, the testimony that I have been able to gather on this point demonstrates that the vagi are diseased in those phthisical subjects which are examined after death. Thus, Dr. Lewin (*Beiträge zur Pathologie der N. Vagus*, 1888), in a minute study of the ganglion of the trunk of the vagus in twenty cases of pulmonary tuberculosis, found it degenerated in every instance.

The foregoing facts, figures, and inductions establish, I think, the truth of the proposition that the link that binds pulmonary phthisis to insanity and to other neuroses is disease of the vagi. This connection furnishes a key to the problem why pulmonary phthisis, a developmental disease, should occur in organs that undergo no development at the time of greatest prevalence of the disease. It also shows why asthma should naturally be transformed into pulmonary phthisis; it furnishes the reason why pulmonary phthisis is at least three times as common among the insane as among the sane; and why it is about eight or ten times as prevalent among families burdened with either idiocy or hysteria in some of their offspring, as in those not so burdened. Indeed, this is precisely what the theory predicts and demands. It does even more than this. It explains why idiots die of pulmonary phthisis ten years earlier than healthy persons. This is accounted for by the fact that a depraved brain and nervous system, such as obtain among this class of unfortunates, offer less resistance to disease than a healthy brain and nervous system. On the same score it accounts for the fact that those that inherit pulmonary phthisis die three years earlier than those that acquire it. It offers at least a partial solution to the question why pulmonary phthisis is more prone to show itself in the insane, than is insanity to show itself among the phthisical. Insanity is an affection of the highest nerve-centers, and pulmonary phthisis, if this is granted, is an affection of the respiratory, and hence of the lower centers; pathology teaches that, as a rule, disease of the higher nerve-centers is more prone to implicate the lower centers than is disease of the latter to implicate the upper. The same law holds true of other neuroses. There are, for example, choreic and hysterical insanities; yet comparatively few choreics and hysterics are insane. Locomotor ataxia is associated with paresis, yet few typical ataxics suffer from insanity.

The view advanced furthermore explains why pulmonary phthisis is excited by many of the influences that give rise to insanity. In the differential etiology of pulmonary phthisis and insanity it appears that less depends on the nature and character of the causes than on the susceptibility of the organism on which they operate. For example, it is conceivable from what we know of this subject that the cause that gives rise to pulmonary phthisis in one individual may, by acting on another with an innate tendency to nervous or mental disease, generate asthma, hysteria, or insanity, and possibly pulmonary phthisis subsequently. So, in the same way it interprets why the age that is most productive of pulmonary phthisis should be between twenty and thirty. It is well known that grief, anxiety, disappointment, excessive mental and physical strain, alcoholism, syphilis, and excesses of all kinds are as potent factors in the production of pulmonary phthisis as they are of insanity. When man attains the age of twenty-five he falls a victim to pulmonary phthisis, not because there is a developmental change going on in his lungs, but because new functions have to be developed to assist him in adapting himself to another mode of life. He is confronted by civilization, with its education, knowledge and inventions; its diverse manners and customs; its changeable institutions; its rankling politics; its innumerable arts, sciences, and manufactures; its multiplicity of industries and employments; its burning life-struggles; its accompanying proneness to vices, excesses, and abuses of all sorts—all of which demand of him the exercise of the highest attainable mental qualifications in order to attain its standard and preserve his well-being. He is like an animal on which are imposed new conditions incidental to a succession of geologic changes, and to which it must adjust its organ-

ization in order to maintain its existence. His new environment is not of the same character as that of the animal, but its power is just as real and as great. The brunt of the battle at this time falls principally on his brain and nervous system, for they are the instruments through which he adapts himself to his new relations; and if from any acquired or inherited weakness these prove inadequate, he will fall in the combat.

In view of these premises, it is not to be wondered at that any influence that impairs the efficiency of the nervous system, no matter whether it is a mental or a physical strain, whether syphilis or poisoning from alcohol, mercury, lead, or brass, whether the virus of diphtheria, measles, scarlatina, whooping-cough, influenza, etc, will also be productive of pulmonary tuberculosis; although we must not overlook the fact that the disease is also generated by auto-tuberculous infection, by traumatism, and by the inhalation of stone-dust, and other particles of matter; nor is it surprising that those that are already burdened with a neurotic taint should go down first, and in the largest numbers; nor need we be astonished to learn that the aborigines of North America, Australia, and New Zealand are being decimated and exterminated by pulmonary phthisis in their unequal warfare with modern civilization.

I think that we are justified in concluding, then, that in genesis and in nature, pulmonary phthisis is so closely related to insanity and to the other neuroses that it may be regarded as one of the branches of the family tree to which they belong. In spite of the fact that occasionally there may be alternation or transmutation between these diseases, thus emphasizing their specific alliance to each other, we must bear in mind that there exists a constant and living difference between all of them. An individual does not become phthisical, insane, epileptic, idiotic, or asthmatic as a result of indifferent material and conditions, but because the inherited influences combine with the exciting causes in his environment and predetermine the variety of his affection; and so long as these remain constant, that long will his disease remain typical. No one is more conscious than I am of the imperfections and shortcomings with which the neurotic theory of pulmonary tuberculosis is here presented; and in order to compensate for this deficiency I shall, in closing, quote the pertinent and philosophic remarks of Dr. Clouston on this subject: "The coincidence of the maximum age of tubercular lung infection, and of greatest liability to one of the most important of the acquired insanities, that of adolescence, is a very striking fact, and taken together with the facts as to heredity, seems to show that if tuberculosis cannot itself be called a neurosis, it is in most cases dependent for its existence on a trophic neurosis, or has the closest affinity to it" (p. 92).

THE IMPORTANCE OF SURGICAL TREATMENT FOR LACERATION OF THE CERVIX UTERI.[1]

BY AUGUSTUS P. CLARKE, A.M., M.D.,
OF CAMBRIDGE, MASS.

THE opportunities now afforded the gynecologist in any case for studying the effect of laceration of the cervix uteri leave but little doubt that treatment is a most important subject for consideration. Experience has, however, demonstrated that the local application of the various agents that have from time to time been suggested as being remedial or beneficial is at best but a temporary expedient.

Whenever a laceration occurring at the cervix extends through the internal and external muscular tissue, the mucous coat lining the canal suffers materially from the violence. The *plicæ palmatæ*, which have been described under the term *arbor vitæ*, undergo serious disturbance in their relation to the other tissues with which they are connected. This condition often leads to congestion, thickening, and to induration of the parts involved and to more or less hypertrophy and malnutrition of the higher uterine segments, and to changed relation and to displacement of the lower cervical zone.

When laceration occurs at the cervix, not only are the muscular and the mucous structures injured, but the mucous glands that so freely abound in the uterine canal also become disturbed in their normal functional activity. It is especially in the cervix uteri about the *arbor vitæ* that the mucous follicles, which when in a healthy condition afford only moderate moisture for the maintenance of their function, pour forth an altered, perverted or diseased secretion. The arteries and arterioles entering into these structures often become preternaturally developed or enlarged; there will often be found a greater interlacing or anastomosing of these vascular structures. This condition may lead to more or less local edema, which the venules and lymphatics will fail to overcome. The structure of the uterine nerves, particularly those derived from the hypogastric and sacral plexuses, becomes so deeply involved that not only do the parts in immediate contact with the torn or injured surfaces become the source of much trouble, but all the tissues forming the uterine body may continue so heavily congested and become so thickened, indurated, and globular as to constitute that condition which has so aptly been termed subinvolution of the uterus. The treatment best adapted for the relief of the suffering that occurs in every such

[1] Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

case, according to my experience, is that afforded by surgical measures. The history of the following case illustrates in some measure the importance of such treatment.

Mrs. C., thirty-six years old, descended from good stock, was originally of sound constitution and in good health. Her *embonpoint*, though fair, was not excessive. She was a sextipara. The eldest child was eleven years old, and the youngest three years old. At the time I was first called, December 14, 1891, there had been a most profuse uterine hemorrhage. On my arrival I found that the patient was blanched; her pulse was exceedingly weak and easily compressible. The cardiac sounds were feeble and gave indication that there was some dilatation and perhaps fatty degeneration of the heart. The patient had for the most part been regular in her catamenial flow, though she had suffered at times from unusual loss of blood. There was no evidence in the history of the case to show that the patient was suffering from the effects of abortion or that she was pregnant, or at any time had ever suffered from a miscarriage.

A few days immediately preceding the date of my attendance she had been doing some extra household work and had attempted to lift some heavy articles of furniture. This may have been the exciting cause of the hemorrhage. Vaginal examination revealed that the cervix was patulous, that it was hard and unyielding, and that multiple cervical lacerations had evidently long existed. There was also an old perineal laceration, which might have contributed somewhat to her inconvenience. By tamponading with iodoform-gauze, the hemorrhage was brought under immediate control.

On the next day a thorough vaginal examination showed that there was subinvolution; the depth of the uterine cavity was six and a half inches; there was also cicatricial ectropium of the cervix to an unusual degree. For some days the use of the tampons was continued, though there was no further hemorrhage.

The patient subsequently suffered severely from facial and supra-orbital neuralgia, sometimes on the left side, and at other times on the right. She also suffered from right-sided sciatica, which from time to time became a source of much distress. Full and repeated doses of morphine and of other opiates often afforded marked relief; stimulants were well borne and were frequently required to overcome the narcotic effect of the soporifics. On December 22d, the patient suffered from a severe attack of gastralgia, which yielded only to morphine administered hypodermatically. Under careful regulation of diet and with the judicious use of stimulants the patient from this time forward gradually improved, though she was kept in bed in consequence of the local inconvenience from which she suffered whenever she stood or was in the erect position.

On February 3d, with the assistance of Dr. A. H. Tuttle, the patient was etherized and placed on the table for surgical treatment. All details of the operation were carried out under strict antiseptic precautions. The uterine cavity still measured six and one-half inches. This was first curetted; then the cervix was repaired. Aseptic animal sutures were employed. The mucous tissue of the lacerated perineum was then dissected up as far as the sulcus on each side; coaptation of the torn surfaces of the perineal tissue was effected by the employment of the same kind of aseptic animal suture. The deep sutures were first inserted; each layer of tissue was brought together in its proper order; last of all the edges were approximated by the buried suture, and the parts, united, were sealed with collodion and iodoform. The wound was protected by dressings to the cervical, vaginal, and perineal tissues.

The patient rallied well from the ether, though more than the average quantity had to be used to overcome all rigidity of the genital tract. The bladder was catheterized at regular intervals to prevent the repaired tissues from becoming contaminated by the discharge of the urine. The patient suffered very little from the effects of the operation; there was no elevation of temperature. She experienced some trouble from a return of sciatica, though this occurred on the left instead of on the right side. Neuralgia in the face and in other parts was at intervals complained of. The woman took nourishment and stimulants freely until the evening of the 12th of February, when she began to suffer from dyspnea; the pulse became irregular and the heart's action at intervals was labored. Though the patient was able to continue the use of nourishment and stimulants, she died during the evening of the fourteenth of February.

An autopsy was held twelve hours after death. On opening the chest the heart was found to have undergone more or less fatty degeneration; both ventricles were somewhat dilated; the left contained an ante-mortem clot. The lungs were congested. The liver gave indication that it also was undergoing fatty degeneration; the spleen, however, was normal. The right kidney was congested and was darker than normal; the left showed that marked organic changes had for some time been going on, and that it was approaching a condition of parenchymatous inflammation. At the cervix uteri, where the lacerated tissue had been brought together by the operation for repair, the parts were in a healthy condition; the line of union had nearly healed. The uterine canal also presented a healthy surface; it showed that all the fungoid granulations had been removed by the curetting. The uterus showed that there had taken place a rapid retrograde metamorphosis of tissue, for the canal itself now measured scarcely four inches in depth. Firm union had already taken place at the line of coaptation in the torn perineum. There was no indication of sepsis about the parts. The autopsy, which had been carefully conducted, did not give the slightest indication that there had been any septicemia or that any other morbid process had occurred as the result of the surgical measures undertaken for the patient's relief. The autopsy further showed that there was no pelvic or uterine tumor and nothing to indicate the existence of a carcinomatous growth, as had been suspected by some of her previous medical advisers.

In view of all the facts connected with the case, it seems fair to conclude that the cause of death was the excessive loss of blood that occurred immediately before my first visit. This loss of blood necessitated the horizontal position for a long time and must have hastened the degenerative changes that had before been insidiously developing. It is also fair to infer that had the operation for her relief been instituted before the lapse of so many years, during which she had suffered from hemorrhage and from other untoward symptoms, her life might have been prolonged.

In another case of cervical laceration occurring during labor, the patient suffered much from endocervicitis and from uterine hemorrhage. After coming under my care, she had intended to submit to an operation, but had delayed the matter, owing to a succession of cases of illness that appeared in her family. The patient suffered much from the subinvolution and from the local inconvenience whenever she travelled or was about the house. She had grown stout, but her flesh was soft from a lax habit of the body. Auscultation revealed that, though there was no distinct cardiac murmur, the two sounds were weak and that dilatation and fatty degeneration had begun to take place. Another severe uterine hemorrhage so prostrated her that she had to be confined for some weeks to her bed. She suddenly died from degenerative changes occurring in the cardiac tissue.

In this case there can be no doubt that had surgical measures been adopted for her relief before she had lost so much blood, the fatty degeneration of the heart's structure would not have been accelerated by the recumbent position, which she also from time to time was frequently enforced to assume. In cases in which the disturbance is greatest at the cervix uteri, operation for repair will often yield most favorable results. In such cases it is surprising to see how speedily the thick and indurated tissue at the cervix softens and relaxes under the influence of the stimulus imparted by operative interference. The venules and lymph-vessels, which seemingly had long since lost or suspended their function, almost immediately take on renewed activity.

In a case of cervical laceration to which I was recently called, there was but little that could be expected to be achieved by the adoption of surgical measures on account of the unusual hypertrophy of the tissues that had taken place, and also on account of the exhausted condition of the patient. The operation was, however, undertaken. I was happily surprised to find that I had succeeded in effecting much toward the reduction of the induration and toward bringing about restoration of the cervix.

In cases of cervical laceration before the structures become indurated or cicatrized, the ectropium or eversion of the tissues of the os uteri may be the chief indication for which surgical treatment is required. Eversion, when present to any great extent, almost always gives rise to much local suffering, especially when the patient assumes the erect position. Such a condition of the cervix is sometimes the cause of sterility; it often interrupts the marital relation.

In a case to which I was called in consultation some two and a half years ago, the tissues of the os uteri so projected forward as to give the impression to the medical attendant, when the examination was made without the help of the speculum, that a fetus at the period of four months or more had engaged in the cervical canal. This patient had been the mother of four children, during the birth of the last of which laceration of the cervix occurred. As a consequence of this injury she had had repeated and troublesome hemorrhages—apparently unassociated with the catamenial flow. This case had, under temporizing treatment, dragged on for upwards of three years. A resort to trachelorrhaphy was followed by marked amelioration.

Emmet, as is well known, long ago expressed his belief that nearly all cases of uterine epithelioma or cauliflower growth have their exciting cause or origin in laceration of the cervix uteri. According to Emmet the carcinomatous development arises from perverted nutrition, in Nature's attempt to repair the injury.

Professor Graily Hewitt, of London, and other eminent authors have expressed the opinion that injury to the cervix by labor is the predisposing cause of uterine carcinoma. In a case that has recently come under my care the history showed that there had been a cervical laceration dating back some ten years. The patient was forty-six years old, and a multipara. There had been considerable induration and eversion. From the history it could not be learned that carcinoma had ever appeared in her family. The patient for several months previously to the manifestation of carcinoma in the cervix uteri had lived in a family in which there were two cases of carcinoma.

In another case to which I was called, the patient was twenty-nine years old and a primipara. There was no evidence of malignant disease in either branch of her family. One year previously she had experienced the initial symptoms of carcinoma of the cervix. She had devoted much time to the care of a friend who was suffering from carcinoma of the breast. She had incurred a cervical laceration during labor five years previously. She experienced considerable inconvenience from the effects of the laceration, and had from time to time received

local treatment; no operation for repair of the cervix was, however, ever undertaken.

In many cases of laceration of the cervix the induration that takes place is limited to an exceedingly small section; the eversion may occasion but little disturbance. In such cases there may have been no arrest of the action of the absorbents that are engaged in the removal of the provisional material incident to pregnancy. In some cases of this class, it would seem that the occurence of laceration increases the activity of the absorbents, or at least helps to expose them to the agency of the *materies morbi* or to that of the disease-germs that at any time may gain admission into the vaginal introitus. As more evidence has of late been adduced to show that carcinoma in its various manifestations is a contagious[1] affection, a much stronger plea than heretofore can now be made in support of the advantages to be gained by resort to the operation for repair of the cervix in which laceration has occurred, though it be of a minor grade.

DISARTICULATION AT THE HIP-JOINT—A NEW METHOD OF CONTROLLING HEMORRHAGE DURING THE OPERATION.

By H. W. BOONE, M.D.,
SURGEON TO ST. LUKE'S HOSPITAL AND LECTURER ON SURGERY IN THE MEDICAL DEPARTMENT OF ST. JOHN'S COLLEGE, SHANGHAI, CHINA.

MR. TREVES, in his manual of operative surgery, calls "this amputation the most serious the surgeon can be called upon to perform." Speaking of methods of controlling the hemorrhage, he prefers the anterior racket incision, in which no tourniquet is applied. He says of the external racket method, that the elastic tourniquet can be applied, and he gives many good reasons for commending it as an excellent operation. Up to the present time the two best methods for applying the elastic tourniquet to the limb have been those of Mr. Jordon Lloyd[2] and the method of Dr. Wyeth.[3] A recent article by Dr. Keen,[4] of Philadalphia, gives an interesting description of the use of Wyeth's method, together with details of the form of operation used by Dr. Keen.

In the method of Mr. Lloyd, "the ends of the bandage thus tightened must be held by the hand of an assistant." One needs a skilled assistant. He may be in the way, and his hand must not slip, as it is liable to do while the limb is freely moved about during the operation. Dr. Wyeth's method is certain, and the control of the hemorrhage is absolute. The drawbacks are the need of two stout steel pins, twelve inches long and one-fourth of an inch in diameter at the head, and the injury to the soft parts of the limb in thus transfixing it in two places.

The plan of securing the elastic tourniquet that I propose is as follows: Get a new pair of suspenders of non-elastic webbing, such as men wear to keep up their trousers. Surround the sound thigh at the groin with a soft handkerchief, folded to make a band, and which has been made antispetic. Put the knot on the outer side of the limb, pass two stout tapes, eighteen inches long, under this band in front, and also one behind the thigh. Fasten these loops of tape through the two button-holes in the front straps of the suspenders and the one button-hole at the back of the suspenders, on the sound side of the body. Lay the patient on his sound side; then put two tapes, about five inches apart, along the trunk and the back of the thigh that is to be amputated; keep them in place by the hands of an assistant, or by adhesive straps across them; lay two tapes, five inches apart, along the front of the thigh and abdomen, and keep them in position. Pure elastic tubing, half an inch in diameter, is then wound five or six times around the thigh, keeping it well up at the very highest point at which it can be applied; then secure by tying it. Take the two posterior loops of tape in the hand and tie one tape securely in each one of the posterior suspender-straps. Take the two anterior loops of tape in the hand; fasten them through the two front button-holes in the front straps of the suspenders, and then let the assistant tighten up the suspenders by drawing the straps through the buckles, while the surgeon is elevating the elastic tube from the body and drawing it further upward. In this way the surgeon can adjust the elastic tube to suit himself. It is firmly held; cannot slip, and it needs no assistant to look after it. He can slack up the tube and cut the tapes whenever he wishes to do so. In this way the punctures through the thigh are avoided. At the field hospital, after the battle, or in the country, where surgical appliances are not to be had, the surgeon who can get one pair of non-elastic suspenders and a rubber tube, or even a strong pair of elastic braces to wind around the thigh, is provided with all the apparatus needed for controlling hemorrhage during the operation.

I hope that practical surgeons will give this method a trial by applying the apparatus to some strong, healthy man. After they have applied it once or twice they will be able to judge whether or not this very simple plan would prove to be of real service in controlling hemorrhage during a disarticulation at the hip-joint.

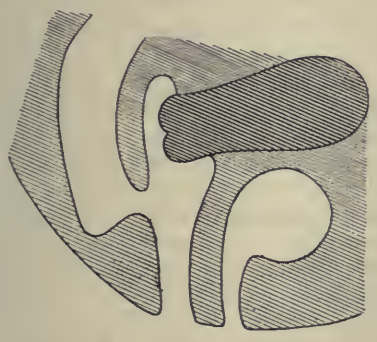
CLINICAL MEMORANDA.

REPORT OF A CASE OF ATRESIA ANI-VAGINALIS; SUCCESSFUL OPERATION.

BY THEOPHILUS PARVIN, M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

INSTANCES in which, according to the common expression, the rectum opens into the vagina, though infrequent, are not absolutely rare. Schurigius, for example, in his work, *Muliebra Historico-Medica*, Dresden and Leipzig, 1729, adduces several cases, derived chiefly from writers in the seventeenth century; and Garrigues (*American System of Gynecology*) states that Pooley has compiled thirty-eight cases. Auvard, from whose work, *Traité Pratique de Gynécologie*, 1892, the accompanying illustration, slightly altered, has been taken, designates the condition recto vaginal fusion. This name

FIG. 1.



suggests a process of mal-development rather than the condition that really is present—an arrest of development.

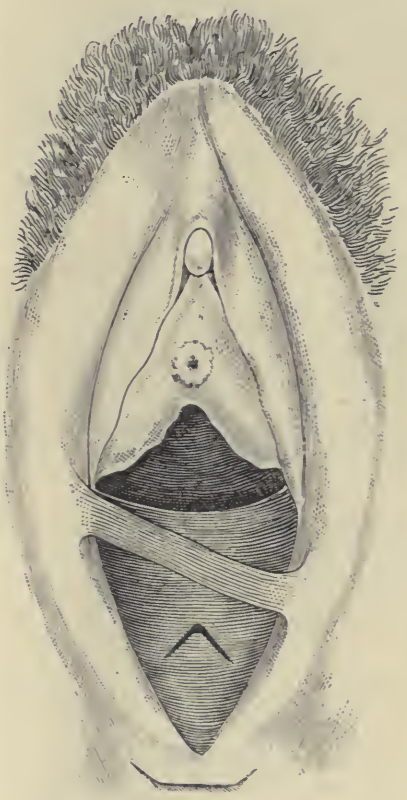
According to Kölliker, about the middle of the third month of intra-uterine life the orifice of the cloaca is divided into two—anal and uro-genital—though embryologists are not clear as to how the separation is effected. De Sinéty speaks of a proliferation of connective tissue situated between the intestine and the canals of Müller, which then open into the posterior wall of the allantoid; there is found a projection, which, little by little, elongates, advancing more and more to the exterior, in order to form the recto-vaginal wall, which isolates the rectum from the uro-genital apparatus, and its inferior part makes the perineum. The perineum is formed in the fourth month. Manifestly, therefore, the absence of the perineum—or, in other words, the opening of the rectum into the genito-urinary sinus—is not a malformation, but an arrest of development occurring in the latter part of the third or in the beginning of the fourth month.

The patient whose case is here narrated was referred to me by my friend, Dr. John H. Brinton. She had twice been operated upon—once in infancy and again at puberty—but unsuccessfully. What these operations were her friends could not inform me, and the surgeon who performed them has been dead some years. Probably the only vestige of an operation is to be found in a band stretching obliquely over the vulvar opening, and which is represented in one of the illustrations. The description of the condition presented by the patient has been written by Dr. Eads, resident physician in Jefferson Medical College Hospital, under whose care she was, and to whose assistance in the operation and assiduous and intelligent subsequent attention the success is largely to be attributed.

Miss E. L., twenty years old, a dressmaker, was admitted into Jefferson Hospital, November 6, 1891. The patient was very anemic. Menstruation began when she was thirteen years old; it was scanty and irregular. She had no evacuation from the bowels without a previous enema, and the movement was attended with pain. Purgatives acted unsatisfactorily, causing only slight watery discharges.

Upon local examination, the genital fissure was found to be abnormally long; the external genitals were apparently normal, except for a narrow band extending from

FIG. 2.

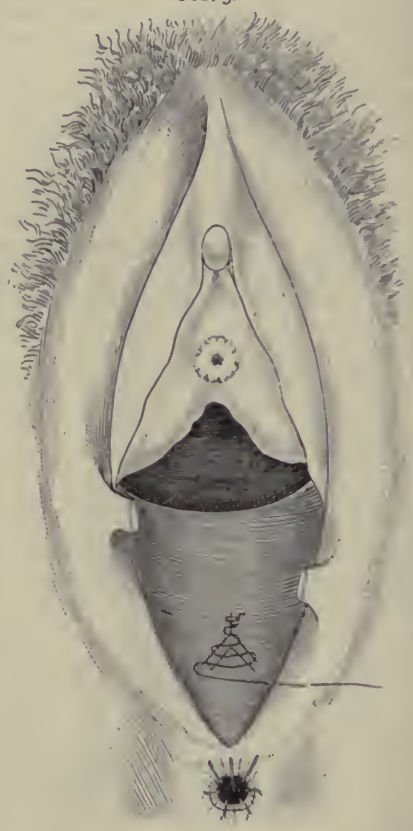


one labium majus to the other, about an inch and a half from the clitoris. There was no external opening of the anus. Within the posterior commissure, and nearly an inch above, there was an opening in the posterior vaginal wall in what appeared to be a capacious cul-de-sac; this opening was guarded by a triangular flap, the attached portion of which was broad, but the free extremity narrow and pointed. Upon introducing the finger into the orifice, a contracting sphincter was to be felt. Upon passing a probe into the opening, it penetrated above some eight inches, apparently coming in contact with the invaginated sigmoid flexure; but directed downward and pressed firmly, its bulb could be felt through the tissues externally.

The accompanying illustration shows fairly the appearance presented by the vulva and the lower portion of the vagina; it shows the band that has been mentioned and the unnaturally located anal opening. In addition, there is presented the first step in the operation performed for the relief of the abnormality.

In considering a suitable method of operating, it seemed to me that the great length of the genital fissure might be lessened by having a flap pushed forward at its posterior boundary. Acting upon this view, a transverse cut and two oblique cuts were made with scissors, these incisions being similar to, though shorter than, those made in Tait's operation for partial rupture of the perineum. It would have been better had the two posterior oblique cuts also have been made just as is done

FIG. 3.



by Tait s method. The transverse incision was carried upward posteriorly to the inferior portion of the rectum, and then completely around its vaginal opening. The next step was by means of tenacula to draw the anus down externally to the middle of the transverse cut; a continuous catgut suture united the anus with the skin, and, in addition, several interrupted silkworm-gut sutures were introduced. (The latter, but not the former, are shown in the illustration.) A continuous catgut suture was used to close the gap left in the vagina. The first operation was almost, but not quite, a complete success, a part of the anterior margin of the anus failing to adhere—a failure that was readily remedied by a re-denudation and suture. In a few weeks, the patient returned home, well. In March she revisited the hospital to tell me how well she was and to testify her gratitude for what had been done for her. She has gained twenty pounds in weight; menstruation is regular; the bowels move twice a day; the evacuation is painless, and there is complete control over gas and feces.

In conclusion, I believe that if the operation had been completely like that of Tait for perineal rupture, so far as incisions were concerned, the result in regard to size of perineum would have been better (the distance between anal and vulval openings is only about half an inch in this patient), for, with the resulting quadrangular surface, skin and subcutaneous tissues could readily have been drawn from the lateral boundaries of the quadrangle, so that the anterior flap would have been pushed further forward. So impressed am I with this theoretic opinion that, were a similar case to be presented me, I would employ the method outlined.

INJURIES TO THE HEAD.

BY WILLIAM M. LEWIS, M.D.,
OF LOS ANGELES, CAL.

WHEN I was a boy, ten years of age, I fell from a horse, fracturing my frontal bone in two places. The four-inch cut in the forehead was sutured—that was all of the treatment. Recovery was prompt.

Shortly after that I saw a soldier strike a comrade with his fist a blow immediately above the left ear, and death resulted in an hour. The treatment was venesection.

These two incidents, more especially the first, made an indelible impression on my youthful mind, and throughout my student and professional life I have tried to learn upon what the element of danger depends in cases of head-injuries. Bryant states that "all injuries to the head should be treated with extreme care, and *always regarded as serious.*" (Italics mine.)

I have read somewhere that no injury to the head is so slight but that there is danger, and none so grave but that there is hope. No rule or law can be laid down to govern these cases. Every case must be a law unto itself.

CASE I.—In 1885, J. D. was struck on the frontal bone, at the edge of the hair, by a companion, with a foot-adze (a cooper's tool). The result was a depressed fracture, nearly four inches long, and hemorrhage sufficient to occasion syncope. Two hours afterward, the depressed bone was lifted to its place, when arterial hemorrhage again threatened the life of the patient. Other means proving useless, the bone was allowed to press upon the brain and the bleeding ceased. The patient had not lost consciousness, except when he fainted. He was advised of his danger and put upon ergot and cold compresses. This treatment may be criticized as bad surgery, but the patient made an uninterrupted recovery, and is alive and well to-day, a deep depression being the only result.

CASE II.—In an altercation with his brother, T. M. was struck on the head with a small scaly rock, receiving a wound that bled only a few drops. No impression was made on the general system, and the patient paid no attention to his hurt. Twenty days afterward, inflammation of the diploë set in, and was rapidly followed by meningeal inflammation and death.

CASE III.—While engaged in compressing a radial artery of a small boy, severed in opening a fruit-can,

my attention was called to a street fight in front of my office; as I looked, a strong, muscular teamster plunged a pocket-knife into his adversary's brain, at a point near the junction of the sagittal and coronal sutures (bregma). The blade sank to the hilt, and in extracting it the assailant used all his power and wrenched it from side to side three times. When the three-and-a-quarter inch blade was finally withdrawn, arterial blood, in a solid column, flew high in air, and the victim sank to the ground unconscious. When I reached his side he was exsanguine and pulseless, and bleeding had ceased—in less than five minutes. A wound of the arm was sutured and the patient was taken to a hotel, stripped of his blood-soaked clothing, his head enveloped in iced cloths, and ergotine, gr. ij, administered hypodermatically. In six hours paralysis of the opposite half of the body was complete; the pulse reappeared at the wrist and signs of reaction set in. In eighteen hours the patient opened his eyes and asked for a drink of whiskey. During the three weeks of illness that followed, the paralysis gradually subsided and recovery became complete. Now, two years and a half after the reception of the injury, the patient is in perfect health, and smokes a strong pipe almost constantly. The amount of brain-tissue that was disorganized must have been considerable, and the loss of blood was measured by the capacity of the heart to pump it out. The man belonged to that innumerable throng around which no surgeon can place antiseptic precautions, while the opportunity for infection was constant; still he escaped.

CASE IV.—In play, a schoolboy, ten years old, was struck upon the head by a small falling rock which his companion had tossed into the air. There was no abrasion and very slight contusion. On the third day afterward, severe headache set in and continued. On the seventh day the usual symptoms of meningeal inflammation developed, and death closed the scene in less than three weeks from the day of injury. A reviewer might say that the traumatism and the fatal illness were merely coincident, but the impartial judgment of the physicians concerned in the case attributed death to the head-injury. Unfortunately no post-mortem examination was permitted.

CASE V.—J. M., sixty years old, while asleep in bed, was struck by an insane person two blows with an axe. The ball or blunt end of the axe was used, and the first blow landed on the side of the head, half an inch above the left ear. The sleeping victim turned partly over and received the second blow transversely across the forehead, an inch above the eyebrow. The entire arch of one eye was fractured loose and hung down nearly an inch lower than that of the other side. At least a tablespoonful of brain-matter had oozed from the gaping wounds and ran down on the man's face, and blood was flowing freely from both ears. Loose fragments of bone were removed, and the battered head was shaped up, and with a few stitches and strips of adhesive plaster the man was made moderately presentable. During the toilet, brain-matter was washed and wiped away freely. Deep stupor, with very shallow and slow respiration and slow pulse, continued for four days. The patient then showed slight signs of rallying, and after two months of illness made a good recovery—only a slight degree of mental impairment remaining four years afterward.

CASE VI.—A. C., thirty-five years old, was thrown from a buggy by a runaway horse. In addition to a cut on one foot and dislocation of two fingers, he received a wound about one inch long, some two inches above the inion, in the middle line. Upon washing the wound a stellate fracture was observed. No symptoms of internal injury were present; the patient was conscious and conversed freely. Convalescence seemed well established, and for three or four weeks not a symptom occurred indicative of any deep-seated injury to the head. At the end of that time mental aberration and motor and amnesic aphasia supervened. The usual symptoms of general diffuse inflammation of the meninges rapidly followed in succession. In consultation, it was decided not to trephine at the seat of injury, as the symptoms pointed to injury by *contre-coup* in the frontal lobes. The post-mortem examination disclosed a large abscess at the seat of injury and another on the upper surface of the right frontal lobe. Trephining and draining the posterior abscess would not have saved the patient.

CASE VII.—While riding along the road, M. W. was fired upon and received a bullet in the left side of his head, at the anterior inferior angle of the parietal bone. The post-mortem examination, made thirty-six hours afterward, showed that the bullet had been deflected downward, had passed through the brain, and had lodged against the temporal bone on the opposite side of the head. Notwithstanding this injury, the man dismounted, climbed over a fence, and pursued his assassin twenty or thirty yards, in fact until he received another bullet, this time in the abdomen. He then went back to his horse and rode two miles. To the physicians who attended him he repeatedly said that the wound in his head was insignificant. He remained rational as long as he lived, and never manifested the slightest symptom of brain-injury. The cause of the death was hemorrhage into the abdominal cavity from a severed small artery.

In this series of cases one feature is most noticeable, that is, that when hemorrhage was free the patients recovered, even though there was loss of brain-substance. Should all injuries to the head be regarded as serious? Should a physician treat every case of head-traumatism as serious?

A few weeks ago I was called to see a man who had received a severe blow on top of the head with a blunt instrument. When I reached his side he was vomiting, and plainly in a state of shock. I regarded the case as serious, and advised him to remain in bed five or six days. On the following day he went about his business. Of course, such a case proves nothing, but it indicates that the physician ought not to be precipitate in action.

I knew a surgeon who had made extensive preparations to do the operation of trephining for depressed fracture. With grips and boxes and bottles and assistants, he approached the house of the patient only to find that the latter had gone out of doors.

INTOLERANCE TO POTASSIUM IODIDE.

BY J. T. BRINGIER, M.D.,
OF BURNSIDE, LA.

F. G., thirty-eight years old, a mulatto, was ordered five grains of potassium iodide, three times daily. After

taking the second dose he was suddenly seized with intense pain in the forehead, eyes, and teeth, with hypersensitiveness in the area of distribution of the trifacial nerve.

There were also marked edema of the eyelids, injection of the conjunctivæ, lachrymation, and profuse nasal discharge.

All the symptoms abated within three days upon suspending treatment. When medication was resumed one week later, only half of the original dose being exhibited, the symptoms recurred, but in a modified form.

THERAPEUTIC NOTES.

The Management of Gout.—In a clinical lecture at the Vienna General Hospital, NOTHNAGEL (*Internationale klin. Rundschau;* 1892, No. 10) stated that the diet of the gouty patient may contain green vegetables and fresh fruits. Sugars and starches are to be avoided. A little meat may be allowed; white meats are preferable to red meats. Active physical exercise is to be encouraged; the action of the skin is to be stimulated by baths and friction. In the treatment of the diathesis alkalies and alkaline waters occupy a prominent place. The lithium salts, well diluted, are useful, permitting, as they do, the formation of soluble combinations of uric acid. Recently, with the same end in view, piperazin has been strongly recommended. In the attack, applications of cold or heat, blood-letting, fomentations of narcotic substances, ointments of opium, have in the past been employed; but these are now usually abstained from, as experience has taught that by energetic treatment the condition may be transformed into atonic gout; at most, inunctions with an ointment of cocaine are made. During the attack, the administration of an acid, like phosphoric acid, has been recommended; and in the intervals between attacks, sodium salicylate. Other remedies failing, colchicum may be resorted to in vigorous doses, conjoined with a narcotic, if warranted by the intensity of the pain.—*Centralbl. für die gesammte Therapie*, 1892, x, 5, p. 271.

A Modification of the Pasteur Method of Treating Hydrophobia.—MURRI (*Lancet*, 1892, No. 3588, p. 1231) reports the case of a healthy, robust man, twenty-two years old, who, after having been bitten by a rabid dog, placed himself under treatment by the Pasteur method of injecting subcutaneously emulsions of the medulla of inoculated animals. On the twenty-fourth day, however, symptoms of hydrophobia appeared. The subcutaneous injections were continued in doses of increasing strength, but without avail. It was, therefore, decided to have recourse to intra-venous injections. For several days, the condition of the patient remained unchanged. Then improvement slowly set in and continued until permanent recovery was practically assured.

Treatment of Carcinoma Uteri.—At a meeting of the Royal Society of Physicians of Budapesth, SCHULZ (*Wiener medizin. Presse*, No. 15, p. 598) reported satisfactory results from the treatment of carcinoma of the uterus by means of interstitial injections of absolute alcohol. From fifteen to thirty minims are injected daily. The patient need not be kept in bed. When the injection is attended with much pain, as when made in the cervix, a narcotic may be necessary. After the injection, the vagina is packed with iodoform-gauze, which is permitted to remain until the following injection. As a result of the treatment, the growth undergoes diminution in size, and pain, hemorrhage, and secretion are lessened. When the tissue has become so hard that it is difficult to introduce the needle, the treatment may be intermitted for the time being. Twelve cases have been treated in the manner outlined. Three have been relatively cured. The others were uniformly improved. The method of treatment is especially applicable when a radical operation is contra-indicated.

Lactic Acid as a Prophylactic in Gout.—BERENGER-FERAUD (*Journal de Médecine de Paris*, 1892, No. 15, p. 181) recommends the employment of lactic acid to prevent the gouty attack. To six hundred grains of the acid is added sufficient water to make a solution of twenty teaspoonfuls; each teaspoonful will thus contain thirty grains. Every morning a teaspoonful of the solution is added to two or three glasses of sweetened water and drunk in the course of the day. At the end of twenty days the medication is suspended for ten or twelve days, and then resumed. The treatment should be continued for several years. The remedy is inoffensive, and does not interfere with the digestion or the nutrition.

SATURDAY, JULY 16, 1892.

THE PROPOSED REVISION OF THE CODE OF THE AMERICAN MEDICAL ASSOCIATION.

THE Committee on Revision of the Code of Ethics of the American Medical Association has before it a most important and responsible task. It doubtless desires all the light upon the subject that any and all can give it, and THE MEDICAL NEWS will gladly open its columns to short and pithy communications upon the subject. In order, however, to make our symposia valuable, we reserve, together with the privilege of opening the discussion and of bringing it to a close when we think the proper time has arrived, the further right to direct the discussion from time to time into special channels.

Thus, the fundamental question that must be decided before particular sections of the code, or particular methods of revision are discussed, is whether or not there shall be a code.

Our own view is, that for the present, being confronted with a condition, and not a theory, a code is necessary. We think, too, that it should be as brief and as pointed as possible.

However, there is much to be said on the side of "No Code." It is true that an honorable man does not need written statutes to tell him what he shall do and what he shall avoid, and, unfortunately, it is equally true that the letter of the written code often fails to hold the rascals. All are familiar with the fact that men whose aims and methods are in no essential particular different from those of the frank quack have acquired and maintain proud position and powerful influence in medical societies, conventions, and colleges. The argument drawn from this lamentable state of affairs is, that as the code has failed to prevent such triumphs of chicanery, it is useless, and that what is useless had better be abolished. In further advocacy of the abolition of the code, attention is directed to the medical officers of the United States Army and Navy, who are not subject to the code of the American Medical Association, but are governed by the military tradition that conduct "unbecoming an officer and a gentleman" is not tolerable; and the deservedly honorable repute of this picked body of men is offered in evidence of the elevating influence of the no-code practice.

Without desiring to forestall the more extended discussion we have invited, we must, however, briefly point out what seems to us to be the fallacy of both the arguments cited. It will certainly not be considered as an ungracious reflection on the medical officers in the service of the United States to call attention to the fact that the conditions of admission to that service are such that they who enter it may be justly considered a "GIDEON'S band;" and in view of their small number it is perfectly justifiable to further assert that from the ranks of the members of the American Medical Association in civil life—and thus subject to the code—a much larger body of men could be picked of equally honorable repute and blameless life.

But even more than this, the code under which military surgeons serve is far more stringent than that of the American Medical Association. We should gladly welcome an amendment to the constitution of the latter body providing that no one shall become or remain a member who may be guilty of "conduct unbecoming a physician," *if* we could only be certain that it would be enforced with the same rigorous certainty that attends the proceedings of courts-martial. Establish an efficient court-medical, clothed with plenary jurisdiction and power, composed of men as upright and as indomitable as the medical officers of the United States Army and their compeers in the leadership of the American Medical Association; support that court by fearlessly giving it work to do—and there is

work in plenty—and then, indeed, will a written code become superfluous. But this touches the very heart of the matter. The reason that the code has measurably failed to prevent dishonorable practices by clever dissimulators is for lack of efficient machinery to enforce its prohibitions, and for lack of courage on the part of honest men to set in motion even the cumbersome machinery provided. The power of Professor A, the influence of Editor B, are forces that we shrink from opposing, or we indolently and weakly prefer peace without honor, to the fatigue, vexation, and publicity of war for the preservation of honor. Let the weakest and most obscure—if he be a man of honor—invoke the penal provisions of the laws of any county society subject to the code, and Professor A's power will be broken and the influence of Editor B be as futile as it proved at Detroit when Philadelphia and Pennsylvania so frightened the nostrum manufacturers and their journalistic allies that, despite their wordy threats before the meeting, they dared not come out of cover when the challenge was thrown down. The greatest weakness of the no-code argument, however, is that it looks only at one side; it studiously shuts its eyes to the fact that, even as "hypocrisy is the tribute that vice pays to virtue," so the dissimulation forced upon Editor B and Professor A is a striking tribute to the deterrent influence of the code. It fails to note that men equally base, but less clever, are compelled to avoid many tempting byways of unprofessional conduct; and that even the master-minds of chicane are not bold enough to go so far as their desires would else lead them.

Utopia and the millennium may rejoice in the absence of penal statutes and police, but even Philadelphia would hardly be a desirable place of residence to-day if anarchy prevailed.

STERILIZED MILK FOR THE POOR.

UNDER the above heading the New York daily papers recently printed an appeal from "A Committee of Public-spirited Women" for contributions of money to purchase a larger sterilizing plant, to supply sterilized milk to the children of the poor. It stated that during the previous summer the Committee had entered upon the business of manufacturing, bottling, and distributing such milk at a price slightly below the cost of production, and had supplied 45,000 bottles to 575 sick children.

The appeal does not mention that these children had been benefited by the substitution of sterilized for natural milk, but appears to take for granted that the use of sterilized milk secures immunity from the summer diseases of children, and is a great boon and certain advantage.

It may, however, seriously be questioned whether such is the case. The opposite ground is taken in an important article recently published by DR. EDWARD P. DAVIS in the *American Journal of the Medical Sciences*. The disheartening results obtained in the artificial nutrition of the infants at the Philadelphia Hospital induced him to make a very exhaustive study of the results obtainable by the use of sterilized milk. The results at the outset, he states, when the food of the children was changed from common to sterilized milk, were very startling and gratifying. Many very sick children quickly recovered, and, for a time, that most perplexing problem—the artificial feeding of infants deprived of breast-milk—appeared to be solved. But later on, most serious and baffling disorders supervened. The children who at first had fattened and thriven on sterilized milk became emaciated and anemic; grave intestinal disorders, which resisted every form of medication and treatment, appeared, and finally, these sterilized-milk-fed children perished of non-nutrition.

In the same connection, an elaborate investigation by DRS. LEEDS and CONN, in the last report of the Dairy Commissioner of the State of New Jersey, is of much interest as throwing some light upon the causes of the great mortality alluded to. They find that the prolonged heating of milk to the temperature of the boiling-point of water brings about numerous changes in its composition and properties. The most important alteration is the conversion of the soluble albumin into an insoluble modification, which is difficult of assimilation and digestion. The trouble usually experienced when cow's milk in its natural condition is used in infant-feeding is that its curdy constituent cannot be digested. This difficulty is aggravated when the non-curdy portion, or soluble albumin, is thrown into a semi-curdlike state by strong heating.

These authors strongly insist that bacteria are not naturally present in milk, and that there is no proper excuse for allowing them to get into it. Their presence is mainly due to lack of cleanliness of the cow, the stable, the person milking and handling the milk, and of the vessels in which the milk is preserved and transported. The true remedy

is to be found in an organized system of official dairy inspection and sanitary milk-control. The inspection should begin with the cattle, and should determine whether they are tuberculous or otherwise diseased. The control should begin with the milk in the udder, and follow it all the way to the consumer.

The rapid growth of knowledge and public opinion will probably lead before long to our State Legislatures taking some steps in this direction. In the meanwhile LEEDS and CONN recommend that market-milk should be Pasteurized and not sterilized. Instead of heating to 212°, the temperature of milk during Pasteurization is brought only to 155°F. At this temperature the bacilli themselves are mainly, if not quite, destroyed; and, whilst the spores of the bacilli are more resistant and require the higher temperature for their destruction, the period of their development is delayed. Market-milk after Pasteurization keeps fresh and sweet for thirty-six or forty-eight hours longer than the same milk as at present handled. Most forms of disease-germs also perish under this treatment. As for those that are not killed, it is wiser to risk the remote contingency of their being present than to convert all the milk into an unnatural product in order to get rid of them. This is the view taken of the matter at the Philadelphia Hospital, where the Pasteurized has been substituted for sterilized milk.

REVIEWS.

A SYSTEM OF PRACTICAL THERAPEUTICS. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Assisted by WALTER CHRYSTIE, M.D. Vol. III. Diseases of the Skin; Diseases of the Nervous System; Diseases of the Genito-urinary Apparatus; Diseases of the Eye; Diseases of the Ear. With illustrations. 8vo, pp. 1352. Philadelphia: Lea Brothers & Co., 1892.

THIS, the third and last volume of the System of which it forms a part, bears out the promise of the first volume. In the completed work we have presented a mirror of modern therapeutic practice, reflecting great credit upon all concerned. The profession is to be congratulated upon having such a work placed in its hands. The various aspects of therapeutic medicine have been presented in a way such as they never have been before. The articles, as a rule, are representative of the most advanced therapeutics of the day. An encouraging feature lies in the fact that the recommendations for treatment do not consist in a mere recital of drugs, but that all means of treatment are given with laudable detail, and as far as possible the rationale accompanies the recommendation.

The present volume contains thirty-seven papers by different authors, dealing with a much larger number of sub-subjects. The limits of this review will not even permit of individual mention. The average value of the contributions is high. Evidences of lack of rigid scrutiny are here and there detectable. On page 231 we find *hydriatic* for hydriatric—a not uncommon error. We are not aware of any authority for the word *perls* on page 239. On page 256 the name *Captain* appears for Cattani. In the table of contents and on page 259 we find Amyotrophic Lateral *Paralysis*. On page 287, Dawbarn, referring to Loomis, is quoted as recommending "aconite as bleeding the patient into his own veins"; while on pages 1231 and 1232 Hare, *A Text-book of Practical Therapeutics*, is credited with saying that veratroidine "so dilates the blood-paths that a man is bled into his own vessels." On pages 316 and 317 the names Strümpell and Möbius appear improperly without the dieresis. The illustration of papillitis, on page 1011, is described as p*u*pillitis with circump*u*pillary exudation. We doubt the wisdom of perpetuating the term "choreic" as descriptive of the movements seen in cases of infantile hemiplegia. Athetoid seems a preferable designation. These movements possess a peculiar vermicular character not observed in the jerky movements of chorea.

PSYCHO-THERAPEUTICS; OR, TREATMENT BY HYPNOTISM AND SUGGESTION. By C. LLOYD TUCKEY, M.D., Member of the Medico-Psychological Association; Membre Fondateur de la Société d'Hypnologie, etc. London: Baillière, Tindall & Cox, 1891.

THE author dedicates his book to Dr. Liébeault, of the Nancy School, from whom he imbibed a love of the study of hypnotism, and of whom he is an ardent admirer and an earnest disciple.

The fact that the present volume is the third edition of the work, the first of which appeared January 1, 1889, is strong evidence of the widespread interest taken by the profession in hypnotism during the past few years.

Dr. Tuckey holds that medical men who would give the subject a fair study should go to Nancy rather than to Charcot's clinic in Paris, where hypnotism is looked upon as a toy and not as a therapeutic agent of any value. The author submits (and we think with great reason) that in view of the fact that such high authorities as Charcot, Richet, Hack Tuke, Heidenhain, Krafft-Ebing, and Tamburini assert that hypnotism is a reality, it can no longer be doubted that the phenomena may actually be induced. At the famous school of Nancy it is claimed that any person can be hypnotized if the proper methods are employed and trials enough be made. The author admits that many evil consequences may follow the employment of the agency by ignorant and unauthorized persons, but claims that these dangers are insignificant when the measure is employed by educated physicians. The cures effected by it are, Dr. Tuckey believes, as permanent as those effected by any other means. Many readers will, however, doubtless take *cum grano salis* the statement that menorrhagia, moral depravity, neurasthenia, and sciatica have been cured by hypnotism.

Although the author is a strong advocate of the claims of hypnotism, it must be admitted that he has presented the matter very fairly, being animated by a

lofty scientific spirit. He is familiar with the works of all the writers upon the subject, as evinced by his frequent references. The *Revue de l'Hypnotisme*, a periodical devoted to the subject, is freely quoted. The work is a most interesting one and deserves to be widely read.

OUTLINES OF ZOÖLOGY. By J. ARTHUR THOMSON, M.A., F.R.S.E., Lecturer on Zoölogy in the School of Medicine, Edinburgh; Joint Author of the "Evolution of Sex"; Author of "The Study of Animal Life." With thirty-two full-page illustrations. New York: D. Appleton & Co., 1892.

IN these days of active biologic research, well-written handbooks in any department of biology are always in demand, and are always welcome. We have such an one in the very inviting little volume on zoölogy just published by the distinguished Edinburgh scientist, Professor Thomson. Tastefully bound, well printed and in clear, attractive type, with the text illustrated by over thirty diagrammatic figures on plates, this work at first sight cannot fail to please the eye of the student in the biologic laboratory. And, indeed, in its nearly 650 pages, rounded off with its admirably arranged index, our author has certainly succeeded in presenting in good, systematic, as well as scientific, style a very excellent outline of the subject of zoölogy as it is now understood by our best zoölogists. More important than all, the work bears the stamp of the mind of a practical teacher and an actual worker in the laboratory; in other words, it is not a closet-compilation, gathered together simply for the purpose of sale, but, as its author states in his preface, is to be used "as an accompaniment to several well-known works cited in the introduction, most of which follow other modes of treatment." We find the work to be morphologic as well as physiologic, founded upon the firm basis of the law of evolution, with the main characters of the principal types of living animals strongly defined and compared, the whole being frequently summarized, throughout its pages, in the most useful kind of tables. In its twenty-five chapters Professor Thomson has not neglected, too, to clearly touch upon such important points as paleontology, geographic distribution, and natural classification, all of which are tersely handled with great skill. Our space will not admit of a criticism in detail, but it will admit of our saying that the work before us is an able guide to the subject of which it treats, and that such few imperfections as it may possess another edition can easily eliminate.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-third Annual Session, held at Detroit, June 7, 8, 9, and 10, 1892.

SECTION OF DERMATOLOGY AND SYPHILOGRAPHY.

FIRST DAY—JUNE 7TH.

The Chairman, DR. L. D. BULKLEY, of New York, read an address on "Recent Advances in the Treatment of Diseases of the Skin," in which he reviewed the remedies recently introduced into dermato-therapy.

Reference was made to the employment of antipyrin in the treatment of neurotic eruptions and pruritus; of pilocarpine for forms of seborrheal disorder; of potassium iodide for psoriasis. The subcutaneous injection of mercury (especially the insoluble salts, as the salicylate) in syphilis was highly recommended.

DR. L. A. DUHRING, of Philadelphia, criticised the statement that in dermatitis herpetiformis no remedy is of value. He finds that sulphur is most useful. An ointment of sublimed sulphur and oil, in the proportions of 8 : 100 may be employed.

DR. RUSSELL, of Utica, N. Y., expressed the view that sodium salicylate is more valuable than antipyrin in the treatment of pruriginous affections.

DR. LOUIS A. DUHRING, of Philadelphia, read a paper on the "Treatment of Acute Vesicular Eczema," a disease, he stated, that is frequently seen by the general practitioner. The remedies used often aggravate the disease. The affection generally appears suddenly, and demands active local treatment directed to the relief of the congestion and the cell-proliferation. The mode of applying the remedies is the important factor. In acute erythematous eczema washes are tolerated better than salves, and pastes are more useful than salves. In acute vesicular eczema, mildly stimulating washes, followed by salves or pastes, are preferable to washes alone. "Rubbing in" and friction are usually harmful. The regulation of the distribution of the blood and lymph, and a direct, local sedative action upon the cutaneous nerve-filaments, are the two most important effects desired. One of the best remedies is modified black-wash, followed by the use of cloths spread with oxide of zinc ointment or paste, two or three times daily. The wash should be diluted with one or two parts of lime-water, and a little mucilage of tragacanth added. A solution of boric acid is useful, especially when the horny layer is absent. Weak resorcin or salicylic acid washes are soothing. A plasma of five parts of tragacanth, two parts of glycerin, and ninety-three parts of boiling water is tolerated when fats are objectionable. A lotion holding in suspension prepared calamine, ʒss; oxide of zinc, ʒss; glycerin, ɱxv; lime-water, fʒiv, and to which may be added resorcin, tincture of coal-tar, carbolic acid or ichthyol—all weak—is valuable. The best ointments are diachylon, freshly made from purest olive oil; oxide of zinc and bismuth; refrigerant "cold creams" containing water are also of service. Dusting-powders are not so useful. Cleansing agents should be used cautiously and sparingly. Rest, for the circulation of the fluids, is of importance, especially when a large surface is implicated.

DR. C. P. RUSSELL, of Utica, read a paper entitled "Eczema of Infancy and Childhood, with Special Reference to Etiology and Dietetic Treatment," which is to appear in a subsequent number of THE MEDICAL NEWS.

DR. OHMANN-DUMESNIL, of St. Louis, read the paper of DR. GEO. T. ELLIOT, of New York, on "A Note on Reflex Eczema in Infants." He stated that eczema of reflex origin occurring in infants is easy of recognition and susceptible of differentiation from eczemas of different pathologic origin. Its localization is most characteristic, occupying, as observed in over three hundred cases, invariably and in a symmetrical manner, both cheeks, rarely the scalp, and when on the extremi-

ties, occurring on the extensor surfaces and not on the flexors. The wrists and backs of the hands are frequently affected, but the trunk only exceptionally, and then in severe and protracted cases. The eruption is always in the form of circumscribed patches, constituted by the aggregation of numberless papules or vesicles, or papulo-vesicles, the aspect of the entire patch being herpetiform. The itching is most intense and leads to scratching and tearing. Etiologically, gastric or gastro-intestinal, or intestinal disturbances alone are found, or dietary irregularities, quantitative or qualitative, or dentition, or even slight cystitis, intestinal worms, etc.; in many cases an adherent prepuce acts as the exciting cause of the cutaneous process.

The eruption will vary in accordance with the presence or absence, removal or recrudescence of one or another of the reflex causes, this variation occurring from day to day or several times a day. At one time the eruption is almost completely gone, and a few hours afterward it recurs in its original intensity. If examined with care it will always be found that the relapse has been preceded by some return of the original reflex cause, or by the development of some new one. The cases originating from the condition of the prepuce are the most intractable, because little attention has hitherto been given to this as a cause, and because it is not suspected or looked for.

The importance of differentiating these cases from other cases of eczema lies in the indications for treatment. This latter is not represented by a specific, but has to be directed against every possible condition apparently or possibly acting as a reflex irritant. In consequence, the systemic health, the hygienic and dietary conditions of the child should be brought up to the normal, and every precaution should be taken to guard against the return of any disturbance, functional or otherwise. The remedies are indicated by the conditions existing, and should vary in accordance with the requirements presented, but in every case they are the same as would be used in the absence of a cutaneous eruption. When every reflex cause has been excluded, and only an adherent prepuce is found, this should, if possible, be stripped back; otherwise circumcision should be resorted to. The treatment is thus entirely directed to the removal of the reflex cause, and the local treatment is purely accessory and of minor importance. Salicylic acid, gr. x, ad ungt. zinc. oxid., ℥j, is as good an application as any. If there is much itching and only little weeping, liquid pitch, ℥j, or fluid extract of ergot, ℥j, may be added, oftentimes with benefit.

DR. L. D. BULKLEY, of New York, read a paper "On the Diagnosis and Treatment of Eczema Seborrhoicum."

In the discussion of the four preceding papers, DR. OHMANN-DUMESNIL, of St. Louis, Mo., stated that he believed eczema seborrhoicum to be dependent upon some constitutional condition. The eruption is most pronounced on the hairy chest of man, especially in the presence of excessive perspiration. The disease is probably an inflammation of the sweat-glands. A zinc salve will help only momentarily. Resorcin has been found useful.

DR. GARRY stated that he suffers with eczema seborrhoicum of the scalp, which disappears readily in cold weather on the application of a resorcin preparation, but in warm weather is more obstinate.

DR. BULKLEY stated that he has also noticed that eczema seborrhoicum seems aggravated by warm weather. It is probable that in warm weather the parasite on which the disease depends finds more propitious conditions for vegetation, perhaps on account of the perspiration.

DR. SHOEMAKER stated that he has found hamamelis, alone or in combination with water or glycerin, the best remedy in the treatment of vesicular eczema. In seborrhoic eczema constitutional treatment seems indicated, together with external applications.

DR. RICKETTS stated that in seborrhoic eczema he has had the best results from a 15 per cent. ointment of ammoniated mercury. The scalp may be rubbed with a stimulating lotion. An ointment of mercuric iodide, too, has likewise given excellent results.

DR. DUHRING expressed his doubts as to the entity of seborrhoic eczema. Many cases are improperly so called. Eczema is often complicated with seborrhea of the face and of the body. In some cases the eczema, in others the seborrhea, predominates.

Dr. Duhring referred to a case of seborrhea in which red plaques appeared on the face, cheeks, mouth; the patient never complained of any itching. The condition disappeared after a few local applications, but it soon recurred. Cases of this class are usually not cured, but only relieved. Seborrhea is not contagious, and is not dependent on the presence of a parasite. Eczema seborrhoicum is to be treated locally; it is likely to get well with the use of resorcin. Eczema, on the contrary, is not relieved so easily.

DR. RAVOGLI expressed the view that it would be well to do away with the name eczema and substitute another more expressive, such as catarrhal dermatitis. Nothing is gained by prefixing the adjectives erythematous, vesicular, pustular, etc. What is wanted is an adjective indicative of the etiology of the affection; thus, nervous, seborrhoic, tuberculous, parasitic.

Dr. Ravogli reported a case of nervous eczema in a man who had such an idiosyncrasy to tobacco that whenever he smoked a cigar an eczematous eruption appeared on the back a day later. Cases are of brief duration, but relapses are common. Not many remedies are required in the treatment. Applications of starch powder, repeated every few hours, are the most beneficial; in case the burning sensations and the inflammatory symptoms are very pronounced, applications of cold cloths wrung out of water containing a small proportion of lead subacetate are to be preferred. In cases of seborrhoic eczema, resorcin, from thirty to fifty grains to the ounce, is useful.

SECOND DAY—JUNE 8TH.

Morning Session.

DR. B. MERRILL RICKETTS, of Cincinnati, read a "Report of Forty Cases of Psoriasis Treated Exclusively with Arsenious Acid."

DR. DUHRING said that cases of psoriasis differ decidedly among themselves. Some cases of eczema are scarcely to be distinguished from psoriasis. Psoriasis

sometimes presents characters of an inflammatory process, and arsenic internally would aggravate the condition. In cases of universal psoriasis of a chronic type arsenic is useful. Many cases can be benefited without any internal treatment, reliance being placed only upon external medication. It seems a mistake to designate any remedy as a specific for psoriasis.

DR. CARRIER referred to a case in which pustules appeared, which, after a course of arsenical treatment, dispeared, and the lesions of psoriasis returned. Better results are to be obtained by local means than by internal medication.

DR. BEARDSLEY stated that he has tried copper arsenite with good results. He thinks a combination of both external and internal treatment the most valuable.

DR. RUSSELL reported good results from the use of arsenic in diffuse psoriasis. He proposed the employment of an ointment of ammoniated mercury or of mercuric iodide, of not too great strength, for external applications.

DR. HERR expressed the view that, despite the differences of opinion, the use of arsenic is very valuable in psoriasis. He referred to cases of psoriasis in patients whose nutrition was poor, in which arsenic rendered great service.

DR. SHOEMAKER stated that arsenic is a valuable remedy at times, but it is no specific. The selection of remedies in psoriasis depends upon the type of the disease and its cause.

In cases of psoriasis of an inflammatory type the internal administration of antimony has been very useful. In the chronic form of psoriasis, potassium iodide has given good results. Arsenic can be employed hypodermatically in large doses and also in the form of suppositories.

DR. BULKLEY stated that arsenic is very effective in bullous eruptions, as in pemphigus. To be effective the drug must be given in small doses frequently repeated. A drop of the officinal solution of potassium arsenite may be given every two hours. Chrysophanic acid and pyrogallic acid, mixed with collodion, act very quickly, and are to be recommended.

DR. CARRIER asked if chrysophanic acid acted only topically. He referred to a case in which he applied chrysophanic acid to one side of the body, and the eruption disappeared upon both sides.

DR. SHOEMAKER stated that chrysophanic acid is objectionable as a salve or in solution on account of its staining. Incorporated in soap it removes the scales, acts readily, and does not stain.

DR. RICKETTS, in closing, stated that he had not intended to present arsenic as a specific in psoriasis. The drug does, however, have some influence on the peripheral nerves; it increases the supply of blood and improves the nutrition of the skin. The hypodermatic administration is the most accurate and effective method.

DR. RAVOGLI, of Cincinnati, read a paper on "The Influence of the Nervous System on Certain Disturbances of the Skin."

After a brief physiologic consideration of the action of the vasomotor nerves upon the nutrition of the skin he pointed out how the nutritive process may be disturbed by these nerves, to which the efficient cause of many affections of the skin can be traced. The connection between the trophic nerves and the sensory filaments was dwelt upon, and the fact pointed out that lesions of sensibility of the skin often accompany angioneurotic affections.

DR. RAVOGLI reported three cases, upon which the paper was based, one of maculæ atrophicæ (liodermia), one of atrophy of the pigment (leukodermia), and one of sclerosis of the skin (sclerodermia). All three cases were in persons presenting derangements of the nervous system. The conclusion was reached that the affections were dependent upon the vasomotor nerves, as a result of derangement of the central nervous system. It was held that leukodermia, liodermia, and sclerodermia differ only in degree, but are alike in being atrophic processes, the first involving the pigment, the second the corium, and the third the whole skin.

DR. DUNLAP expressed the view that maculæ atrophicæ present great similarity to morphea.

DR. HERR referred to the case of a young woman, with epilepsy and discoloration of the cheeks, who could not feel the prick of a needle, and who suffered with cephalalgia. In a case of Addison's disease, the patient had no pigment on the hands. On post-mortem examination the suprarenal capsules were found degenerated. Dr. Herr concurred in the view that these diseases are the result of derangements of nutrition.

DR. DUHRING expressed his agreement with the views of Dr. Ravogli. There is no specific treatment. This must be varied to meet the requirements of the case. Dr. Duhring held that the sympathetic nerve is always involved in these cases.

DR. OHMANN-DUMESNIL referred to a case of leukodermia symmetricum in a woman with spinal anemia, and to one of periodic hyperhidrosis in a woman, as indicative of the influence of the symphathetic nerve. In another, atrophy of the skin and of the muscles developed in a girl after a severe burn. A case of warts and alopecia areata was likewise ascribed to nervous disturbances.

DR. BULKLEY reported a case of atrophy of the pigment of the head occurring after nervous disorders.

DR. DUNLAP, of Syracuse, read a paper on "Pemphigus Hemorrhagicus, or Purpura Bullosa," reporting a case of bullous eruptions, of chronic course, with repeated relapse. At first the bullæ were filled with serous fluid, which was subsequently replaced by bloody fluid. The bullæ were preceded by some redness of the skin. The patient did not complain of itching, but of pain.

DR. RAVOGLI commended caution in the diagnosis of pemphigus. Many cases that were called pemphigus are now recognized as dermatitis herpetiformis bullosa, Duhring. The diagnostic characteristics of dermatitis herpetiformis are polymorphism of the eruption, the presence of pruritus, the frequency of relapse, and the condition of apparent health. The case reported appeared to be one of pemphigus. The differentiation is of the greatest prognostic importance, when it is borne in mind that dermatitis herpetiformis is curable, while pemphigus is essentially fatal.

DR. RUSSELL expressed the opinion that, from the history of the case, the polymorphism of the eruption, the relapses, the redness appearing before the evolution of the bullæ, the case was likely one of dermatitis herpetiformis.

DR. DUHRING expressed the view that the case was one of pemphigus hemorrhagicus. Hemorrhage is not uncommon in connection with bullous diseases. Bullæ are sometimes connected with hemorrhagic diseases. Cases of pemphigus are very rare. In the case of a woman at the Philadelphia Hospital a bullous eruption appeared in relation with menstruation.

DR. BULKLEY stated that in New York bullous eruptions are designated as hydroa, while dermatitis herpetiformis is employed to include the atypical cases of vesicular eruptions. Such a case as that reported would be described as hydroa hemorrhagica. Dr. Bulkley would not call it pemphigus because of the failure of arsenic, and not dermatitis herpetiformis on account of the absence of pruritus.

Afternoon Session.

The following officers were elected for the ensuing year: *Chairman*, Dr. L. A. Duhring, of Philadelphia; *Secretary*, Dr. W. H. Dunlap, Syracuse, N. Y.; *Executive Committee*, Dr. L. D. Bulkley, of New York; Dr. D. A. H. Ohmann-Dumesnil, of St. Louis; Dr. A. Ravogli, of Cincinnati.

DR. RUSSELL reported "A Case of Acute Circumscribed Edema of the Skin."

DR. OHMANN-DUMESNIL referred to a case in a laborer who had his finger scratched, and on the following day presented cutaneous edema, which looked like urticaria, being whiter than the normal skin. He bathed the part with a solution of mercuric chloride, and in two days the edema disappeared. Cases of this kind are to be ascribed to an inflammatory process involving the lymphatic vessels, dependent upon a slight infection.

DR. DUHRING expressed the view that there is a close relation between urticaria and acute circumscribed edema.

DR. RAVOGLI stated that he had often seen edema of the skin limited to a certain region, especially of the extremities, but he always found that there was a certain degree of lymphangitis, while careful examination would disclose the presence of a scratch, or an abrasion, or a pustule.

DR. OHMANN-DUMESNIL, of St. Louis, read a paper on "Some Successful Methods in the Treatment of Alopecia and Alopecia Areata," which is to appear in a subsequent number of THE NEWS.

DR. RUSSELL read the report by Dr. Dunn of "A Case of Tubercular Adenitis, with General Alopecia and Pruritus." (See THE MEDICAL NEWS, July 9, 1892, p. 41.)

In the discussion of the two preceding papers DR. WILSON, of Kansas City, reported the case of a letter-carrier who lost the hair all over his body. By the use of pilocarpine in one-eighth grain doses, and electricity, the growth was, in a short time, completely restored.

DR. HERR stated that he has treated a number of cases of alopecia areata, some of neurotic origin; some of parasitic origin. He has at present under treatment a patient with alopecia areata, in which he is using carbolic acid by the method of Bulkley, with satisfactory results. From his experience he is inclined to believe that most of the cases are of parasitic origin.

DR. SHOEMAKER stated that he has found the application of massage and galvanism combined to yield the best results. He objects to the application of pure carbolic acid on account of the pain.

DR. RUSSELL stated that he has not seen many cases of alopecia areata, and most of these were of neurotic origin. He used the French method, rubbing with cantharidal collodion till vesication occurred, then applying a salve of yellow sulphate of mercury, thirty grains to an ounce of vaselin. In other cases he has used chrysophanic acid, thirty grains to an ounce of vaselin, with good results.

DR. DUHRING confessed his inability to distinguish a neurotic and a parasitic form of alopecia areata. He was not aware that he had ever encountered a case of parasitic origin. He places little reliance upon local treatment; the general nutrition is the principal point.

DR. RAVOGLI stated that if atrophy of the pigment and atrophy of the connectve tissue can be produced by disorders of nutrition, there is no reason why the hair should not fall out from similar influences. In most of his patients with alopecia areata a parasitic influence appears to be present. The presence of lanugo hair on the bald spots, with brittle hairs of dark color scattered in tufts over the surface of the scalp, and the unbearable itching, suggest a parasitic origin. In treatment any strong parasiticide is useful. Dr. Ravogli has, with good results, painted the spots with tincture of iodine, rubbed them with crude coal-oil, washed them with a strong solution of sublimate, with glacial acetic acid, treated them with oleate of mercury, and many other antiparasitic remedies. The best results in these diseases is to be obtained by the use of the forceps, removing the lanugo hairs and the stumps of the broken hairs. Most cases of common alopecia are due to the presence of seborrhea, alopecia pityroides. The general nutrition is often impaired. In these cases the application of resorcin is of great advantage, while the tincture of tar will bring the skin back to its normal condition.

DR. BULKLEY stated that a good deal of alopecia is dependent upon seborrhea and is readily corrected by the use of resorcin, from 5 to 6 per cent. in water or alcohol. In every case of alopecia, phosphates and milk are to be given. In cases of alopecia areata in which broken hairs are found, there is no doubt that parasites are present. When alopecia areata is found among several members of the same family this fact is not to be ascribed to contagion, but to exposure to the same hygienic conditions. In alopecia areata Dr. Bulkley paints the spots with pure carbolic acid, repeating the application once a week. This does not produce any considerable pain, and the patients never object to it. The absence of pain is an argument in favor of a neurotic origin. Internally strychnine and phosphoric acid in considerable doses are administered.

DR. OHMANN-DUMESNIL stated that he has applied carbolic acid over an area of ten square inches on the scalp in a case of alopecia areata, without producing much pain, repeating the application twice a week, without any objection on the part of the patient. Parasitic alopecia areata is to be distinguished by the presence of a round area, with small scabs and thin, brittle hair.

THIRD DAY—JUNE 9TH.

DR. W. F. BREAKY, Ann Arbor, reported a "Case of Lupus." The patient was a woman with lupus on the

cheeks and on the nose. Tuberculin was used in treatment. The first injection contained five milligrams, and was followed in eight hours by a temperature of 102.4°, a pulse of 120, and marked local reaction. A second injection was given six days later, and was followed by a temperature of 103.6° and a pulse of 120, with more marked local reaction, with effusion and exudation on the nose and cheeks. After the injections there was some improvement, but subsequently the lupus was worse.

DR. ATKINSON, of Baltimore, stated that there is no doubt that tuberculin has a powerful influence on the tuberculous process, and the results of its employment are rather encouraging. There is no agent that possesses a like power. It seems reasonable to hope for a specific treatment for tuberculosis.

DR. DUHRING stated that his experience with tuberculin has been limited and unsuccessful. He reported the case of a woman, thirty-five years old, with patches of lupus on both cheeks, on the nose, and extending to the throat. The tuberculous infiltration not only involved the corium, but also the subcutaneous tissues, so that it was impossible to pick up the skin in folds. As it appeared that nothing could be accomplished by local treatment, inoculation with cultures of erysipelas were used. The experiment was a failure; no reaction took place. The ordinary superficial patches of lupus can be scraped off and recovery secured, but when the infiltration is deep and extensive, injections become necessary.

DR RAVOGLI related the case of a man with lupus who had been treated in the Marine Hospital in Washington. He took over one hundred injections; not only was there no improvement, but he was actually worse. On the other hand, Dr. Kramer, of Cincinnati, presented to the Academy of Medicine a case of lupus vulgaris in a tuberculous patient that had been treated with tuberculin. At different times various local applications had been made, but without result. Finally the employment of tuberculin was begun, an injection of from one to five milligrams being given every two or three days. The improvement was speedy and decided.

DR. HERMAN GOLDENBERG, of New York, read a paper entitled "Chancre of the Finger, with Special Reference to Adjacent Adenopathy." He related that in some cases of chancre of the finger that he had observed, and that he had found reported in the literature, the axillary glands were enlarged, while the epitrochlear glands were not affected. This appears strange if it be considered that the syphilitic virus spreads by the lymphatics; it would be expected that in all cases the epitrochlear lymphatics should be enlarged.

Lewin, of Berlin, has given an explanation that the deeper lymphatics enter the axillary glands, the superficial ones the epitrochlear glands. Following the description given by Sappey in his elaborate work on the lymphatics, the conclusion was reached that Lewin's theory is not correct, but that the lymphatics of the first three fingers, as a rule, enter the axillary glands, while those of the fourth and fifth fingers terminate in the epitrochlear glands. It is therefore to be expected that in chancre of the fourth and fifth fingers epitrochlear swelling will be found the rule, and not the exception.

DR. RAVOGLI reported a case in which a chancre appeared beneath the nail of the third finger of the right hand. When first observed, there was a pronounced maculo-papular eruption all over the body. The ganglia were universally swollen and the epitrochlear gland of the arm, corresponding with the infected finger, was hard and palpable, while that of the other side was scarcely perceptible. In another case a chancre was found on the inferior portion of the second phalanx of the thumb of the right hand, in a man in whom, from keeping the hands in water, a fissure had formed on the thumb. He also had a maculo-papular eruption, with enlargement of the ganglia. The epitrochlear gland of the corresponding side was enlarged and swollen.

DR. DUHRING reported the cases of two medical men who believed that they had acquired syphilis in surgical work. They had erythematous eruptions, but no chancre could be found. The eruption proved to be not specific.

DR. BULKLEY reported the case of a patient with gonorrhea, who likewise presented symptoms of syphilis. A chancre could not be detected until discovered on a finger, covered by a piece of plaster, the patient believing it only a simple scratch.

In another case, in a man with eczema and a fissure a little above the rectum, an extragenital chancre developed in the fissure. It appeared that the man had taken a sea-bath in a pair of drawers that had been previously used by another person.

DR. LYDSTON stated that it must not be overlooked that there is no syphilis without the preëxistence of a chancre. He related the case of a woman in whom a chancre developed upon the gum from the application of carbolic acid to a carious tooth by means of an infected instrument.

DR. LYDSTON read a paper entitled "Circinate Syphilide, with Report of a Case," which is to appear in a subsequent number of THE NEWS.

DR. DUHRING stated that among a large number of syphilitic patients he had met with many cases of this form of syphilide, especially among the lowest class of persons, with broken-down constitutions and addicted to alcohol. He expressed the view that the nervous system has a good deal to do with the production of this form. Psoriasis presents some similarity to syphilis circinata, especially when on the face and neck, and is to be considered in the differential diagnosis.

DR. BULKLEY stated that it is unusual to see such a form of syphilis in the course of only four months. It may be that the nervous system is at fault.

DR. RAVOGLI contended that the division of the symptoms of syphilis into primary, secondary, tertiary, and quaternary is a mistake, conveying the impression that the symptoms follow one another in a definite succession. The best division is that of Virchow into an early and a late stage, the lesions of the early stage being characterized by inflammatory symptoms, and those of the later stage by infiltration and new growth. Circinate syphilide is but a nodular form, in which small nodules are situated closely together in groups, disposed in half circles or in circles. In the case reported there was probably also a seborrhea, in consequence of which thick crusts formed. The form observed about the hands was nothing else but a psorasis palmaris, of which there are two forms, one papular and the other ulcerative. The circinate forms of syphilis and psoriasis

palmaris are usually obstinate to treatment. Dr. Ravogli stated that he had obtained beneficial results from the use of a bath of corrosive sublimate, the hands being kept in a solution of 1 : 1000 for about one hour daily.

DR. EDWARD PREBLE, of Cleveland, presented a paper "On a New and Practical Mode of Grouping Affections of the Skin, with a Brief Analysis of One Thousand Cases." The following classification was proposed:

I. Deformities (anomalies of embryonal and trophic origin, and secondary acquired and artificial malformations).

a. Redundancies. 1. Simple diffuse hypertrophies (ichthyosis, keratosis, pilaris, hypertrichosis, lentigo, telangiectasis, etc.). 2. Nevi (vascular and non-vascular). 3. Benign tumors (fibroma, lipoma, angioma, steatoma, etc.).

b. Defects. 1. Simple defects or atrophy (albinismus, leukoderma, alopecia, rugæ, atrophia senilis, etc.). 2. Qualitative atrophies and dystrophies (colloid degeneration, myxedema, xanthoma, scleroderma, etc.).

c. Secondary and artificial deformities (cicatrices, pigment-deposits, tattoo-marks, argyria, melasma from malaria, etc.).

d. Persistent anomalies of function (livedo, hyperidrosis, comedones, xerosis, etc.).

II. Injuries (acute dermatitides, acute angio-neuroses, rashes, etc.).

a. Causes external. 1. Inanimate cause (effects of mechanical irritation, chemical irritation, heat and cold, etc.). 2. Animate cause (all forms of suppuration, phlegmon, furuncle, whitlow, impetigo, ecthyma; and initial lesions of specific inoculable diseases, erysipelas, glanders, charbon, vaccinia, chancre, etc.).

b. Cause internal. 1. Reflex source (pruritus, urticaria, etc.). 2. Toxemic source (exanthemata, scarlatina, variola, varicella, etc., drug-eruptions, erythema multiforme, erythema nodosum, herpes iris, pemphigus, purpura, etc.). 3. Neuritic source (herpes zoster and kindred affections). 4. Hidrotic source (lichen tropicus, sudamina).

III. Diseases.

a. Local origin. 1. Occupation-dermatoses (corns, callus, professional eczemas, etc.). 2. Parasitic diseases (scabies, pediculosis, favus, tinea tricophytina, verruca vulgaris, molluscum contagiosum, etc.).

b. Cutaneous phenomena of general, chronic, infectious diseases (syphilis, tuberculosis, lepra, sarcoma, carcinoma, elephantiasis Arabum, etc.).

c. Diseases at present unclassified (etiology complex or occult). 1. Eczema (infantile, capitis, manuum et pedum, cruris, flexuarum, orificiorum, etc.). 2. Diseases located in the follicles of the skin (acne juvenilis, acne rosacea, acne cachecticorum, sycosis, dysidrosis, etc.). 3. All other diseases (psoriasis, lichen planus, prurigo, etc.).

The relative frequency in one thousand cases was found to be: Deformities, 21 per cent.; injuries of local origin, 26½ per cent.; injuries of internal origin, 11½ per cent.; diseases of local origin, 13 per cent.; general diseases, 8 per cent.; diseases of complex or unknown etiology, 20 per cent.

DR. ELISHA CHENERY, of Boston, presented a paper entitled "Experiences with Scabies." He stated that scabies, though laughed at, is an important disease, made so by its active contagiousness, the difficulty of diagnosis and cure. He related the case of a clergyman who took a little girl from a poor-house, and through her transmitted the itch to nearly all of the good families of his parish, embracing parts of several towns. A well-to-do family had scabies from grandmother to baby, and spread the disease because their wealth and station set them above having the itch.

To be successful, the treatment of scabies has to be followed up to all of the affected persons and their infected clothing.

Forty years ago the disease was rare in Boston. Now it is annoyingly present, especially in the low foreign quarters, where it is so firmly entrenched that it is next to impossible to dislodge it. It, therefore, becomes the duty of the Board of Public Health to devise means to thoroughly stamp it out. Its removal is more than the physician, single-handed, can do; so the matter becomes one of public interest, and should so be regarded and treated.

DR. W. H. RIGHTER, of Topeka, Kansas, presented a "Report of a Case of Verruca Papillaris of the Upper and Lower Lips." The case was that of an Englishman, fifty-five years old, who presented large warts or verruca papillaris upon the lips. The lower lip was completely covered with warts, and upon the upper lip there were two large ones. The growths had begun to appear at the age of eighteen, and at the age of twenty-one they were fully developed. The man considered his condition a deformity and an annoyance, and was anxious to have the masses removed. After a week's treatment with the stick of silver nitrate, applied daily, the warts had disappeared, and in another week the lips were restored to their normal appearance.

CORRESPONDENCE.

QUACKERY IN THE TREATMENT OF ALCOHOLISM.

To the Editor of THE MEDICAL NEWS,

SIR: In view of the position taken by you in such matters, I enclose circulars of the Plymouth Institute, of Warsaw, Ind., an institution which, by a three weeks' course of treatment with the "Borton Cure"—"rum's new foe"—originated by Dr. T. A. Borton—guarantees a perfect cure for the liquor and morphine habits. The company modestly claims: "We never fail to effect a cure, no matter how bad the case may be." One point upon which stress is laid is that the patients constantly have access to whiskey, with, nevertheless, "the *positive assurance* that the appetite for it will not outlast the *third day* of treatment."

One evening recently, while Dr. Borton and an agent of the institute, a Mr. Cooper, were in this city for the purpose of starting a branch here, I had an opportunity, with a small company of gentlemen, of meeting them. The conversation became quite interesting and instructive, but did not succeed in developing the enthusiasm and admiration for this institution that was, I suppose, expected.

Dr. Borton stated that the Plymouth Institute has been in operation about two years, and is having a large

patronage. His remedy for the liquor habit he claimed to be a specific, acting by causing in three days such disgust at the taste and sight of liquor that an unconquerable and permanent aversion is created; by some magical effect the taste of these beverages (but not of any other article of diet) is made so disagreeable—"at first as if pepper had been put in"—that the habit is for this reason at once abandoned. The ingredients were stated to be such as could be obtained at any drug-store on a prescription. General treatment is also given. Great stress was laid on the point that the desire for liquor is a disease, not a habit, though how that theory or name helps matters is not clear to my unenlightened mind, as if a disease were necessarily easier to cure than a habit. The institute does not undertake the treatment of persons who are unwilling to be cured, while claiming 100 per cent. of perfect cures of inebriates who desire relief. Applicants with organic lesions advanced to any degree are also rejected.

The morphine treatment consists in the administration of a substitute for the opiates, both being subsequently withdrawn.

In answer to some pertinent questions Dr. Borton could give no valid reason why the medical profession generally could not or should not administer his remedy as well as himself. The most that he could claim was that a slight amount of special study and training were necessary to perfectly qualify physicians to employ his treatment, and that it required considerable personal attention and care, say three calls daily, which he professed to fear physicians would not give. He admitted that the remedy could be applied with ordinary professional skill; that it was only of average potency—stronger than many drugs, but not so strong as numerous others, and that its injudicious or inefficient application would result in no greater harm than the careless administration of many other drugs.

It was suggested that, if his treatment, as he claimed, is or could be made so powerful an agency in diminishing intemperance and its evils, the usefulness to humanity of "rum's new foe" would be vastly increased by publishing it for the use of the whole medical profession, and so making it more generally accessible to the masses suffering from the physical and moral demoralization of alcoholism, and that under these circumstances, keeping the remedy secret for the purpose of holding a lucrative monopoly, thereby contracting its sphere of alleged usefulness, was quite shamefully selfish and decidedly unphilanthropic. On being pushed with these suggestions Dr. Borton seemed embarrassed, or ashamed, and had but little to say. What he did say was to the effect that his course was not, to be sure, quite professional; that his conscience was not quite easy in the matter; that it was a tender subject with him, and that he didn't like to talk about it.

To the suggestion made in his behalf that a person is entitled to the rewards and profits of his inventions and discoveries, it was replied by the gentleman who principally had been showing up Dr. Borton's real motives, and who has been Commissioner of Patents, and is not a physician, and whose opinion on this subject, therefore, deserves great weight, free from any suspicion of prejudice, that the inventions for which the patent system secures certain privileges and rewards are especially mechanical appliances which are not essential to the happiness and well-being of mankind, but are simply additional material conveniences and luxuries; but that, while it is proper to thus encourage such inventions, yet the case is entirely different with agencies that can profoundly affect the issues of life and health (especially those that have such a promise of power and beneficence for the moral and physical well-being of humanity as was claimed for the "Borton Cure"), and no monopoly should be allowed; no restrictions whatever placed in the way of the freest and broadest dissemination and usefulness of such agencies. The gentleman referred to said that he would willingly contribute liberally toward rewarding Dr. Borton for his discovery and helping him disseminate it through the land; but not one cent would he give to send anyone to the institute, and so encourage him in such a monopoly.

This man, therefore, by his own admission, shows that the high-minded philanthropy which he and his like profess and parade is entirely an advertising sham. While no one can prevent them from trading upon men's physical and moral weaknesses, yet their motives should be shown up to the world in all their base selfishness; that their object is not at all benevolence and charity, but solely selfish financial gain at the expense of the great mass of inebriates. There are thousands of temperance-workers who are devoting their time, energy, money, and lives to diminishing the evils of intemperance, and they are doing this unselfishly, gratis, entirely for the good of mankind. A true humanitarian would scorn or never dream of using for purposes of gain a panacea for drunkenness which he might discover, but would give it free to all the world, carrying out the principle that salvation is free. The (alleged) salvation for body and soul offered by the Plymouth Institute comes only at a good round sum.

Respectfully yours, J. BEN NICHOLS.

1419 HOWARD AVENUE, WASHINGTON, D C.

ALCOHOLISM.

To the Editor of THE MEDICAL NEWS,

SIR: Alcohol, in whatever form, either diluted with water, as in whiskey or brandy; or in a solution with water mixed with grape-constituents, as wine; or in the form of fermented liquors made from malted grain, as beer and ale, acts in all of its combinations in the same way, producing the same physiologic effects, which vary in accordance with its proportion. Hence, in speaking of the effects of the use of alcohol, all the members of this group that contain it are included.

Alcohol, when introduced into the stomach, causes a sense of warmth, which rapidly diffuses and is quickly followed by a general glow of the body. In moderate quantities, it increases the secretion of the gastric juice, and in that way assists the digestive power, stimulating the flow of blood, creating a superficial congestion of the mucous membrane, and soliciting a greater supply of the stomach-juices. Large quantities impair digestion by coagulating albumin. Taken in large quantities, alcohol precipitates the pepsin of the gastric juice and destroys its activity as a digestive agent. The habitual use of alcohol produces structural alterations in the stomach, seriously impairing the digestive power, so

that an abnormal quantity of mucus is secreted, and this acts as a ferment and keeps up a gastric catarrh, followed by pyrosis, regurgitation of food, heartburn, etc.

By its great power of diffusion, alcohol enters the blood directly from the stomach, without entering to any great extent the small intestine. The liver is consequently at once influenced by its presence in the portal vein. The functional activity of the hepatic cells is for the time being increased, and a more abundant glandular secretion follows. The first result of the overstimulation of the liver is an increase in size of the organ; but by over-work, the hepatic cells undergo atrophic changes and shrink. The liver becomes smaller, nodulated, and hardened; there results the condition known as cirrhosis or hobnailed liver.

In small doses, alcohol increases the action of the heart; in larger doses, excitement, exhilaration, and slight intoxication ensue; in still larger doses, it causes loss of muscular power, impaired coördination of voluntary movement, and rambling incoherence. In toxic doses, profound insensibility, stertorous breathing, and complete muscular resolution quickly follow. In small doses, all the functions are for the time being more energetically performed; but with the increased action of the agent, the functions of the system become disorderly and uncontrollable. In excessive quantities, the functions of the brain are suspended and complete unconsciousness ensues.

Alcohol has been discovered in the fluid contained in the ventricles, and has been distilled from the cerebral matter. As a result of the direct contact chiefly, but in part also from variations in the intra-cranial circulation, important structural changes are gradually wrought in the cerebral matter. The cells of the gray matter become more or less fatty and shrunken, the neuroglia undergoes hyperplasia, shrinking and condensation of the whole cerebrum ensue, and the cerebro-spinal fluid relatively increases. The objective evidences of these pathologic changes are seen in the impaired mental power, the muscular trembling, the shambling gait of the drunkard. These are a few of the many injurious effects of alcohol, to which may be added delirium tremens, hemianesthesia, epilepsy, paraplegia, amaurosis, etc.; and mental alienation, as asylum statistics show, has in the same agent its most influential cause.

A few well-known physiologic effects have been presented in this communication to show that the excessive use of alcohol is injurious. There are many addicted to the use of alcohol who say they desire to rid themselves of the appetite or disease. Alcoholism is, however, rather a result of habit than of disease, inherited or acquired; and the appetite for alcohol is wholly acquired. To be sure, its continual use will produce a diseased condition of the organization, structural and organic in character; but that derangement is not so much a disease known as alcoholism, as it is a direct destruction of tissues brought about by contact of the alcoholic poison with the organization for a continued length of time. The craving for the alcoholic excitation is not a disease, but a result of habit. This inordinate craving is what is commonly classed as a disease, the removal of which requires specific treatment. This habit is oftentimes induced by dyspeptic disorders, mental depression, or a sense of prostration incident to various diseases, and it is sometimes evidence of a constitutional idiosyncrasy. The power to resist it is impaired in proportion as the faculties of the mind are weakened by indulgence.

Alcoholism is a great curse, and any agent that will help to rid society of it is a good thing; but can any conscientious man, standing in the medical light of the nineteenth century, believe that Keeley, who holds his so-called cure a secret from medical men, and defies analysis, intelligently hopes to confer any real benefit upon humanity in his so-called gold-cure, or has any higher aim than the directing of the gold of the country into his own coffers?

There are few men who really desire to quit the habit of drinking; whose pleasure in drinking is not greater than their desire to reform. Any man, however, who really desires to quit the habit, and will make up his mind accordingly, can easily do so by exerting what little will alcohol has left him; by placing himself under the direct care of an intelligent physician, who will administer appropriate tonic treatment to support his system until it can depend upon the natural stimulation of good nutrition. He will then find himself just in the condition that Keeley or any other man need hope to leave his patient, who has his welfare at heart—only better off, not depending on any so-called cure, but with the knowledge of his condition before him, and knowing well that to falter is to fall.

This habit can only be overcome by sufficiently long total abstinence, together with measures directed to the removal of disorders and to the promotion of mental occupation and invigoration of the body and mind. There is no drug that has a special efficacy.

Respectfully, P. V. Ellis, M.D.

Ghent, Ky.

ATROPINE-POISONING AND THE "KEELEY CURE."

To the Editor of The Medical News,

Sir: The following on criminal poisoning by atropine is from Blythe's *Poisons: Their Effects and Detection*, vol. ii, p. 341: "Criminal poisoning by atropine in any form is of excessive rarity in Europe and America, but in India it has been frightfully prevalent. . . . It was largely used by the Thugs, either for the purpose of stupefying their victim or for killing him; by loose wives to insure for a time the fatuity of their husbands; and, lastly, it seems in Indian history to have played the peculiar *rôle* of a State agent, and to have been used to induce the idiocy or insanity of persons of high rank whose mental integrity was considered dangerous by the despot in power. The Hindoos, by centuries of practice, have attained to such dexterity in the use of the 'datura' as to raise that kind of poisoning to an art, so that Dr. Cheevers, in his *Medical Jurisprudence for India*, declares that 'there appears to be no drug known in the present day which represents so close an approach to the system of slow poisoning believed by many to have been practised in the Middle Ages as does the datura.'"

Apropos of this is the report of an American physician, made to one of the medical journals within the past year,

that his son, as the result of an overdose of atropine, broke down mentally and physically, and died after an illness of about two years. He was rejected on application for a life insurance policy on the simple ground of the atropine-poisoning, and the examining physician adduced three other cases of atropine-poisoning in which the victims died in a few years.

These considerations would seem to throw a strong light on the cases of impaired health and lessened mental vigor of some of those who have gone through the so-called "Keeley cure." The physiologic action of the "cure" named is exactly in keeping with the idea that the active agent is atropine. After a few days' treatment the vision becomes blurred, the pupils dilated, the patient can no longer read ordinary print, and there is profound nervous depression.

The following quotation from Blythe may throw some light on the source from which Keeley drew his inspirations (*Poisons*, etc., vol. i, p. 10): "J. Baptista Porta, in his *Natural Magic*, published in 1589, gives a method *of drugging wine with belladonna root for the purpose of making the loaded guest loathe drink.*"

There can be no doubt of the actual, though temporary, loathing often induced by the "Keeley cure," and as little doubt of its producing the physiologic action of atropine. In some who thereafter succeed in establishing a reasonable amount of will-power, the effect appears to give the requisite start in the right direction; I have consulted with men who had manifestly been rescued by this means from the drunkard's fate, and had maintained their self-control for years. There is reason to fear, however, that, with too many, the susceptible nervous organization that made them at first easy victims of the drink-habit compels them to succumb with equal readiness to the atropine—and the brain being more infirm after treatment than before, they lapse with increasing facility into drink, even if they escape the extreme mental disorder and the physical break-down of atropine.

The Keeley claim of 99 per cent. of permanent cures is doubtless based on the notorious habit of the drinker denying his vice; that a small percentage of recoveries occurs it is but candid to acknowledge. These occur, however, in those only in whom the natural mental power is vigorous, in whom the brain is little susceptible to the action of narcotics, and in whom a strong purpose of resistance can yet be aroused. For the majority of drunkards in whom the susceptibility to narcotics is very great, no permanent cure, or restoration of the will-power so as to control the appetite, can be expected.

If these conclusions are correct, it would appear that the reckless use of this most dangerous drug on a susceptible class of persons should make the administrator responsible for all the evil results, mental and physical, that follow. Were this agent used straightforwardly under its own name, the patient and his friends would be in a position to protect themselves against a poison so redoubtable; but, when used under a false name, it seems as if a cause would lie very strongly against the Keeley doctors, and especially against Dr. Keeley himself.

Respectfully yours,

JAMES LAW, F.R.C.V.S.

CORNELL UNIVERSITY, ITHACA, N. Y

NEW ORLEANS.

Death of Dr. T. G. Richardson—The New Orleans Polyclinic.

PROF. TOBIAS GIBSON RICHARDSON died in this city on Thursday, May 26th, at the age of sixty-five. He had been in poor health for three years, but his last illness was very short. He was Dean of the Medical Department of Tulane University of Louisiana for twenty years, and one of its professors for thirty-one years. At the time of his death he was Emeritus Professor of Surgery. He was elected President of the American Medical Association in 1879, and was an honored member of the Orleans Parish and State Medical Societies. He was noted for his charity. The city of New Orleans has lost one of her most prominent and best citizens, and her physicians have lost an honored and enthusiastic friend. The Orleans Parish Medical Society attended the funeral in a body.

The New Orleans Polyclinic has applied to the State Legislature for equal privileges with Tulane University in the Charity Hospital.

INFLUENZA AND CHOREA.

To the Editor of THE MEDICAL NEWS,

SIR: I see in your issue of May 7th a report of a case of influenza followed by choreic movements in an old lady of sixty-five. My father and myself had a similar case in January of the present year, the lady being seventy-five. The movements were in the right upper extremity and head, and were at times quite violent, so much so as to cause great soreness of the muscles of the neck.

The movements lasted about three weeks and then gradually subsided, the old lady having an uninterrupted convalescence, with the exception of an attack of phlegmonous erysipelas involving the lower lip.

We treated this case throughout with quinine, phenacetin, and stimulants, using iron also during the attack of erysipelas. Inasmuch as the case reported died, I thought this case ending in recovery might be of interest.

Very truly, F. SALE, M.D.

BEDFORD, VA.

TUBE-CASTS AND THEIR DIAGNOSTIC VALUE.[1]

BY I. N. DANFORTH, A.M., M.D.,

PROFESSOR OF CLINICAL MEDICINE, CHICAGO MEDICAL COLLEGE; PROFESSOR OF RENAL DISEASES IN WOMAN'S MEDICAL COLLEGE OF CHICAGO; PHYSICIAN TO ST. LUKE'S HOSPITAL, AND TO WESLEY HOSPITAL, CHICAGO.

THE study of renal tube-casts is not new. Since Henle, in 1842, first comprehended and announced their importance, their relation to renal diagnosis and pathology has been generally admitted.

The exhaustive essay of Bartels, in Ziemssen's *Cyclopedia*, is an excellent record of our knowledge of casts up to that time; but I think something more may now be added.

For some years past I have had occasion to study tube-casts frequently and consecutively for purposes of diagnosis, and, while doing so, have, insensibly perhaps, arrived at certain results and reached certain conclusions which it is my purpose to set forth in this paper. I do not claim any new discoveries, but hope my paper will add something of system and definiteness to the study of casts and something of certainty to the diagnostic conclusions to be drawn therefrom.

Concerning the origin of tube-casts, I think they are clearly of two distinct kinds, each having a different origin, and each indicative of a different pathologic process. First, we have the mucous or more properly mucin casts—and I do not think that casts of this variety have received the consideration to which their importance entitles them. Mucin casts, I would divide into two groups: (*a*) Simple mucin casts, without crystalline or cellular elements; (*b*) Casts that include saline or cellular elements acquired during their formation in the kidney. This division has an important bearing on diagnosis, as I shall endeavor to show presently.

Secondly, we have the true fibrinous casts, or those that have long been recognized and variously classified by different writers; and these may be divided into four groups: (*a*) The hyaline or "structureless" casts, which contain no formative elements whatever. (*b*) Blood-bearing casts; (*c*) Cell-bearing casts; (*d*) Fatty casts.

This classification may be reduced to tabular form, for purposes of systematic study, as follows:

CLASSIFICATION OF TUBE-CASTS.

Class I. Mucin Casts.
- (*a*) Simple mucin casts, entirely destitute of formative elements.
- (*b*) Mixed mucin casts, or those that include crystalline or cellular elements, acquired during their formation in the tube.

Class II. Fibrinous Casts.
- (*a*) Hyaline or structureless casts.
- (*b*) Blood-bearing casts.
- (*c*) Cell-bearing casts.
- (*a*) Fatty casts.

Of course, each group may be divided into subgroups, but such wire-drawn distinctions serve no good practical purpose, while they are likely to confuse and perplex the student.

Turning now to the first class, the *mucin cast*, let us consider its origin and pathologic import. It is certainly not the product of an exudate, and is therefore not directly derived from the bloodvessels. This fact separates it at once and forever, as regards origin and pathology, from the fibrinous cast, a point to which I shall allude again presently.

It is undoubtedly true that the mucin cast is formed within the renal tubules, and from material furnished by the tubal epithelium, most likely by the epithelium of the convoluted tubes. Under certain circumstances, the epithelial cells seem to undergo a change equivalent to the "mucoid degeneration" of Ziegler, the protoplasm of the cell being transformed into a mucoid substance, which is afterward cast into the lumen of the tubule, there to aggregate itself with the similar product of neighboring cells, thus forming the simple "mucin cast" or the long, wavy string of mucin so often seen in urine. The mucin cast is the product of a catarrhal nephritis, a pathologic state to be sharply differentiated from exudative nephritis, with relation to origin, treatment and results.

I have contended for more than ten years that "catarrhal nephritis" ought to have a distinct recognition in our systematic nosology, simply because it is a distinct disease, frequently existing for years and having its own characteristic symptoms and course. The simple mucin cast is the characteristic morphologic product of this disease and establishes its differential diagnosis. Frequently, it is the only reliable indication of the existence thereof, since catarrhal nephritis is not generally accompa-

[1] Read before the Association of American Physicians, Washington, May, 1892.

nied by subjective symptoms of any marked significance.

Together with the mucin cast are frequently found tubal epithelium, leukocytes, and urinary salts, but these have no necessary relation to the pathologic condition indicated by the mucin cast; it alone establishes the diagnosis of catarrhal nephritis.

The "mixed" mucin cast is the "simple" mucin cast plus whatever crystalline or cellular elements may chance to be present. Clinical experience shows that the elements most likely to be present are leukocytes, or crystals of lithic acid or calcium oxalate. The presence of the first indicates that there exists a catarrhal condition of sufficient intensity to induce rapid multiplication of the nuclei of the epithelium, which by reason of the "mucoid" degeneration of the protoplasm of these cells are set "free" and are hence easily enclosed in the mucin cast during its formation.

It may be said that these leukocytes escape from the blood by diapedesis, but if that were true we should have hyaline (fibrinous) casts, instead of mucin casts, since we cannot conceive of a hyperemia sufficient to produce diapedesis without at the same time inviting exudation.

Of course, if hyaline casts *are* present, exudation is proved, and the diagnosis of exudative inflammation is thereby established. It is not at all unlikely that hyaline and mucin casts may be present together, which would show that the case was in a transition state from catarrhal to exudative nephritis, or *vice versa*, as I have seen in many instances; and it is in just such cases as these that familiarity with the appearance of tube-casts, and their diagnostic pointings, is so necessary, since it is impossible to establish a refined diagnosis from any other standpoint.

When the mucin cast includes crystals of lithic acid, oxalates, or phosphates, it is clearly correct to assume that these crystals were deposited in the renal tubules and that they point to a diathetic condition which determined their formation.

From a diagnostic point of view, it is important to note that the crystals are *within* the cast and not adherent to its *surface;* because it clearly warrants the conclusion that they were formed in the renal tubule and not in the pelvis or bladder.

This being the case, we can readily account for the renal irritation that has led to the renal catarrh and consequent renal inadequacy, so common when these diathetic factors are present. The diagnostic value and the importance of recognizing these crystals and of determining their nature and location is thus clearly indicated.

In the year 1874 and again in 1879 and 1880 the late Dr. Mahomed drew attention to "high arterial tension" as a symptom prophetic of chronic interstitial nephritis, and described what he designated as the "pre-albuminuric stage" of chronic nephritis. His writings attracted wide and well-merited attention, but his untimely death occurred before he had completed his researches and experiments. It was his belief that high tension or irritable heart, with contracted and resistant bloodvessels, preceded albuminuria, sometimes for months or even years. It was his further belief that the approach of renal cirrhosis might be predicted by carefully estimating the degree and constancy of cardio-vascular tension, by means of consecutive sphygmographic tracings.

A broader study of this subject has developed the fact that this peculiar condition is not certainly present, except in cases of well-marked lithemia, and that even then, as Dr. Grainger Stewart has observed, some degree of cirrhosis usually precedes the symptom.

Increased or abnormal vascular tension, then, can hardly be regarded as a prophetic or prodromic symptom of renal cirrhosis, although its value as regards differential diagnosis cannot be denied.

I believe, however, that the presence of the mucin cast is of far greater diagnostic value than is high arterial tension under any circumstances.

In the first place, I am satisfied that the great, in fact, the overwhelming, majority of cases of interstitial nephritis are preceded by a long period of faulty digestion and mal-assimilation. This is certainly the case in the vicinity of Chicago, where my observations are chiefly made. This leads to overworked and irritated kidneys, as Dr. George Johnson first pointed out; but more than that, it leads to the development of renal catarrh, as Dr. Johnson did *not* point out.

Vitiated or abnormal urine produces a catarrhal irritation of the kidney, just as vitiated or abnormal ingesta produce a catarrhal irritation of the stomach. The next event is the appearance of the mucin cast long before any recognizable renal lesion occurs, and long before arterio-capillary tension is present in such degree as to be detected, except by the most expert and experienced sphygmographist. In fact, arterio-capillary tension, as a practical every-day symptom for the guidance of the ordinary practitioner, does not yet possess the value that Mahomed, as well as Gull and Sutton, predicted for it. Its recognition presupposes the possession of instruments and technical knowledge not generally possessed by those most likely to encounter the cases to which they are applicable. Moreover, as I have already said, the symptom in question does not usually precede the lesion of which it is an indication. Again, vascular tension does nothing more than suggest a possible diathetic antecedent; whereas it is all-important, if such a complication be present,

that it be promptly recognized and appropiately treated.

I claim for the mucin cast a position of preëminent importance in the early diagnosis of interstitial nephritis; more than this, I claim that the appearance of the mucin cast is a prophecy of that change which is only too sure to follow chronic catarrhal nephritis.

Moreover, the cause or "diathesis" that preceded and led to the catarrhal kidney may generally be detected by the microscopic study of the urinary sediment that falls with the casts, and as this "diathesis" includes or rather *is* the essential pathologic factor in a given case, its early recognition is most important. All this can be done, has been done, is daily being done, by him who is most concerned in all our researches and experiments, namely, the general practitioner. What seems to me a consideration of no small importance is the fact that the recognition of the mucin cast and the crystals or granules of lithic acid are not matters of opinion or guess-work, or questions of comparative judgment, but simply questions of fact and of fact only; these substances are or are not present, and the conclusion is obvious. The degree of arterio-vascular tension in a given case is, however, a matter of comparative judgment at best, and in every case is a very variable factor, present to-day and absent to-morrow.

It is proper, although perhaps needless, to add that the foregoing statements are based on a long and cumulative experience, upon long and careful study of many cases, some of which are still under observation, and are in no proper sense theoretic or conjectural.

I will now ask your attention briefly to the second class, namely, the true *fibrinous casts*. The presence of the fibrinous cast in urine is abundant proof that sufficient hyperemia exists, or has existed, in the kidney to produce exudation of the fibrin factors, and most probably diapedesis. It is proof, therefore, of the presence of "exudative" inflammation, instead of "catarrhal" inflammation, which I have just considered. I regard it as very essential that this distinction be kept in mind, since it has much to do with the question of treatment, and is all-important in its relation to prognosis. In both forms of disease albumin may be present—present at one time, and absent at another. In the early stage of exudative (interstitial) nephritis, the quantity may be so small as to require very careful testing to prove its presence. In catarrhal nephritis the amount is always very slight, many times amounting to no more than a trace. As a diagnostic symptom, therefore, albuminuria has very little value, and no uniform value. Tube-casts, however, have a positive as well as uniform diagnostic value, provided their interpretation is understood. One of the most important points settled by them is the question whether, in a given case, we are dealing with catarrhal or exudative inflammation.

The *hyaline cast*—the first variety of the second class—is the simplest and most innocent form produced by exudative nephritis. It is so small and so translucent that it frequently escapes detection, unless the examination happens to be made by an expert microscopist. Its diagnostic value depends mainly upon its frequency and upon its form or symmetry. If only an occasional hyaline cast is found it goes to show that exudation is very slight; that it is in its incipiency, or has well-nigh ceased—a question that can easily be decided by reference to other symptoms that do not come within the scope of this paper. If many are present, exudation is still going on actively. In my own examinations I lay great stress upon the form of the cast. If it is smooth and symmetrical, or free from "twists" or distortions, it seems to me to indicate that it was formed in a tube not yet disturbed by the encroachment of pathologic connective tissue; but if the cast is not smooth and regular on its surface, and if it shows angularities, as though it had been violently bent or twisted, I am equally confident that the cirrhotic process has already made considerable progress. I regard this a very important diagnostic indication, and one that has helped me very greatly in seeking grounds upon which to found a reasonable prognosis. It will save repetition if I say now and here, that the same observations with reference to symmetry and form apply in equal degree to the varieties of casts that are yet to be mentioned.

Blood-bearing casts indicate a hyperemia sufficient to cause hemorrhage into the renal tubles, although it may be very slight indeed. Hence, blood casts are commonly regarded as proof of acute nephritis, and of that only. In every such case, however, it should be borne in mind that while the blood cast may be the immediate result of an acute lesion, a long-standing chronic lesion may have preceded it, and careful search for other forms of casts should be made. In other words, a prognosis founded upon blood casts alone is quite likely to disappoint the expectations of physician and patient. In every case of apparent acute nephritis careful search should be made for casts indicative of pre-existing chronic disease, and it is not wise to prognosticate favorably until several consecutive examinations have failed to disclose the presence of the casts of chronic nephritis. I have rarely encountered cases of so-called "idiopathic" acute nephritis that were not preceded by undoubted chronic nephritis.

Cell-bearing casts, the "epithelial casts" of authors, are so common, and are generally so well

understood, that little need be said about them, except to emphasize some two or three points. Care should be taken to determine whether the cells adhere to the surface of the cast or are incorporated therein. In the former case they may not be the result of pathologic exuviation, but they may represent only cells wasted by wear and tear, whose escape has been anticipated slightly by the friction of the cast as it passes down the tubule. In the latter case they must have fallen off from purely pathologic causes. The shape or form of cell-casts is as significant as that of hyaline casts. Casts from a cirrhotic kidney are likely to be twisted and distorted; casts from a case of tubal nephritis are likely to be straight, symmetrical, and rather large. In either case the cells may be cloudy, granular, or filled with glistening droplets of fat, thus indicating with great precision the stage or condition of the case under examination, as the more advanced the process of fatty degeneration of the cells the more advanced the destruction of the kidney in which they were produced.

Fatty casts are evidence of the completion of the destructive process of which the hyaline cast marks the beginning. They are more or less numerous as the case is more or less advanced in its ultimate pathologic history. They are more or less eroded and irregular as the tubule is more or less denuded of its epithelial lining, and otherwise roughened in its lumen. They are more or less twisted and distorted as the tubule is more or less pulled out of shape and symmetery by the encroachments and contractions of the pathologic connective tissue. Thus they indicate the stage as well as the form or type of the disease of which they are the product. With fatty casts may be mingled hyaline and epithelial casts; in fact, the three forms are frequently found together. The stage of the disease in a given case would be pretty accurately indicated by the predominating type of casts; but it would be evident that some minor portion of one or both kidneys was either more or less advanced in the pathologic change than the chief portion of these organs.

I have not regarded the *waxy* or *amyloid* cast as entitled to a separate grouping, because it is only an accidental variety of fibrinous cast, presenting no inherent peculiarities of structure, and therefore indicating no pathologic changes in the kidney that are associated with its presence. Waxy casts are almost invariably hyaline or structureless; if they happen to contain the peculiar waxy or amyloid material implied by their name the iodine test will promptly demonstrate the fact, and thus establish the diagnosis of waxy kidney; but clinical experience shows that the amyloid disease can seldom be differentiated in this manner. In conclusion, permit me to add that I have long been persuaded that the course of a given case of acute or chronic nephritis, the type of the disease, the sequence and nature of the pathologic events taking place in the kidney, and the grounds for a reasonably positive prognosis, may be evolved from an intelligent and careful consecutive study of the tube-casts alone. Other factors of course enter into the diagnosis, and their value and importance I do not question, but I believe, with Formad, of Philadelphia, that the tube-cast conveys more actual and accurate information to the practiced microscopist than any or all other symptoms or signs.

ASEPSIS AND ANTISEPSIS AS APPLIED IN THE LYING-IN CHAMBER.[1]

BY WILLIAM WARREN POTTER, M D.,
OF BUFFALO, N. Y.

THE subject that forms the title of this paper has been frequently discussed in societies and medical journals during the past ten years, but definite and fixed rules of action have not been formulated or agreed upon; at least, there has been no unanimity in the profession as to when these methods should be adopted, how far they should be carried on, and when they should cease. It will be my object in the following paragraphs to briefly set forth my own views thereon, and I invite the most searching criticism from the members.

Prior to the introduction of antisepsis, with reference to the practice of surgery, by Lister, we may say that practically nothing had been done to eliminate septic influences from the parturient chamber. The practice of surgery has been almost revolutionized by the teachings of Lister, even though surgeons to-day do not adhere in any considerable number to the precepts that Lister originally laid down; nay, more, even Lister himself has departed from many of his original dicta. It remains, however, and ever will remain a fact, that no man has done more to improve methods and to bring success to the surgical art than this great modern apostle of surgical cleanliness. No sooner had the benefits of his teachings been tested in surgical cases than obstetricians began the application of similar methods in the lying-in chamber. It is easy to understand how advocates of new methods of procedure may readily become extremists, and hence cause harmfulness by their zeal; so, very soon we found the application of antiseptic methods in the lying-in chamber combated by very eminent men.

However much men may disagree as to the necessity for the employment of a particular agent, or as

[1] Read at the Forty-third Annual Meeting of the American Medical Association, in Detroit, June, 1892, and at the Semi-annual Meeting of the Medical Society of the County of Erie, June 14, 1892.

to the methods of its application, all must admit that it would be better if every parturient woman could be made absolutely clean, and all septic germ-influences excluded from the puerperal chamber. How best to approximate, if not to attain, this ideal is a problem that confronts every obstetrician to-day.

Here are a few simple propositions about which there can be, or at least ought to be, no dispute: 1. Let us begin by making the patient as nearly clean as it is possible for soap and water to accomplish. 2. Let her, prior to the beginning of labor, have an immersion-bath daily for several days, and with the first manifestations of pains let her abdomen and genitalia be rendered absolutely aseptic by the further application of germicides in solution, adequate to accomplish the desired end. 3. Let her have a warm vaginal douche, rendered aseptic. 4. Let the lower bowel be thoroughly evacuated by copious lavements of hot water prior to the vaginal bath. 5. Let her bedding be made as pure and clean as careful laundrying can make it. 6. Let her clothing be made equally clean in like manner. 7. Let there be a number of clean bichloride napkins placed in readiness for use. If all of these injunctions are rigidly enforced we have done much to lay the foundation for a physiologic labor.

After all this careful preparation of the patient and her surroundings we have not, however, done enough. The physician and all the attendants must be rendered as scrupulously clean and aseptic as the patient herself, else all the previous preparation has been in vain. The nurse must be a woman of absolute cleanliness, both in the care of her person and her clothing, and she must be especially trained in the habit of keeping her hands clean. The physician must be trained in all the details of aseptic and antiseptic principles, and must enforce his rules as rigidly upon himself as he does upon his patient and her nurse. He must not approach the genitalia with soiled fingers or with unclean apparel. Let him make his primary examination as carefully and as deliberately as possible, to ascertain as to the relations of the woman and the fetus, and then let him refrain from further examination until some special reason arises to make its repetition necessary or imperative. Any repetition of the examination must be practised with the same carefulness that was insisted upon the first time, and so on to the end. If these simple rules are carried out in a normal labor it would seem as though every avenue for the entrance of pathogenic germs had been guarded. After delivery all lesions of the genital tract should be sutured, and a toilet made of the genitalia under the supervision of the physician himself. These are some of the simplest rules that can be named with reference to the care of a case of labor, and who dare say that they should not be rigidly enforced?

My friend, who has an active practice in a rural district, will say that it is not possible to carry out even these simple rules and do justice to his other work that is pressing on all sides. My answer is, let him approximate thereunto as nearly as may be, and decline all obstetric service where a disposition exists on the part of the patient and her friends to ignore such careful directions as may be given them. I know a physician who absolutely declines to take an obstetric case unless he can have at least one or two months' supervision of the patient prior to labor. He will not accept a chance-call to such a case unless it be to relieve a brother practitioner who requests it. If all men would adopt such a rule we would soon find no difficulty in enforcing discipline in the parturient chamber, as well as in making adequate and ample preparations for the ordeal.

In spite, however, of all these precautions, and in their exercise with seemingly rigid care, septic fever will sometimes occur, and then we are often called upon to exercise the highest and most difficult part of our functions. Then comes the test of judgment and the demand for skill. With the temperature running gradually upward on the fourth or fifth day to 103° plus, and with a fetid discharge from the genital tract, can there be any reasonable doubt about the propriety of at once making efforts to render the uterus and vagina perfectly sweet and clean by the employment of intrauterine lavements? It would seem to me as illogical to neglect such a procedure as it would be to fail to remove the dressings and clean out the pus from a fetid surgical wound. Unless this intrauterine toilet be performed with great care, however, there is danger that it will fall short of accomplishing all that may confidently be expected of it when adequately and properly applied.

The latter proposition, namely, the method of performance of the intrauterine toilet, it seems to me is a question of grave importance. It is a delicate task—one that must be performed with the utmost precision and neatness, or else it had better not be done at all. In other words, it must be done with the same exactitude that any surgical procedure entails; let it be done by properly placing the woman on a table in the proper light, with a suitable gravity douche, containing sterilized water, within easy reach, and with all other careful preparations that would obtain in the performance of an intrapelvic or abdominal operation. This has been amply set forth by Dr. Lewis S. McMurtry, in a recent paper[1] and need not be further elaborated here. We often hear it said that even with the careful and judicious employmennt of the intrauterine lavement in the manner indicated it cannot overtake the germs that have infected

[1] Trans. Amer. Assoc. Obst. and Gyn., vol. iv, 1891.

or have been absorbed, and that, therefore, it will not accomplish the purpose sought. In my judgment, this is a specious attempt at reasoning. It may be true that the lavement cannot overtake such pathogenic germs as have already found entrance in the organism, but it can sweep out all colonies that remain unabsorbed, and thus cut off the septic supply. With the further absorption of these germs prevented, the patient will generally go on to easy cure, the exception being only in cases in which the method has been resorted to inadequately or after too much mischief has already been done. We are constantly told by the practitioner in the country that it is impossible to adopt all this precision and exactitude in the exigencies of daily practice. While it must be conceded that there is some truth in this statement, yet I confess that it seems to me an admission of weakness, of which to purge ourselves we must not hasten slowly. If a method is useful or necessary in the saving of health or life, no labor is too great and no caution is too exacting that will put it into process of execution or application. In this brief paper it has been my object to make a plea for greater exactitude on the part of the general practitioner in the employment of both asepsis and antisepsis in the practice of obstetrics.

We have all seen what can be done in the management of large maternities by the application of these principles. A distinguished member of this section has already, in a large maternity, obtained the unprecedentedly large percentage of over a thousand consecutive obstetric confinements without a death. This would have been impossible under the management in vogue twenty years ago. If it is competent to obtain such results in a building in which no other class of patients is received, it would seem to be quite reasonable to anticipate a like degree of perfection in the rural districts, where fresh air and good water are always at hand. What we require is a little more energy, a little more ambition, a little more determination to avail ourselves of the methods at easy command, to make the disease heretofore known as childbed fever one of the past opprobria of obstetric medicine.

To recapitulate, then, let me insist that the elementary precepts of the practice of modern midwifery entail the amplification of three or four principles. The first is that the parturient woman, whether of high or low degree, must be made absolutely clean in her person and surroundings; her room must be clean; her bed must be clean; and everything used during confinement must be free from taint or odor. This law must be insisted upon, even though the environment of the woman denies her luxuries—often even the bare necessities—of the lying-in chamber; but the great God of heaven has not denied her the luxury of fresh air and clean water.

The second principle involved applies with clearly cogent force to the *personnel* of the accoucheur, who must render himself clean with soap and water, supplemented by the free use of a nailbrush and a germicide solution. He must make no physical exploration of the genital tract until he is absolutely certain that he can carry no poison to his patient by such examination. The third principle involved is that the child should receive immediate attention as soon as it is born, so that there may be no danger of sepsis invading its eyes or other exposed parts. Ophthalmia neonatorum must be entirely blotted out, as it can be, provided due care is observed in relation to the management of the new-born. The fourth application of this principle applies to the nurse or other attendants upon the parturient woman. It, perhaps, requires more skill and tact to properly train a nurse to be absolutely clean in her work than it does to enforce the principle in all its other bearings. No nurse can be adequately so trained unless the trainer is himself scrupulously clean and expert with reference to all questions pertaining to the subject in hand.

These are a few practical thoughts that have come to mind, and have been hastily converted into language, without previous opportunity to elaborate the subject in such a manner as it deserves; but if this imperfect presentation of it will lead to a discussion that will be productive of some good its purpose will have been fully served.

If it should be remarked that I have said less of antisepsis than of asepsis, it is because I am of the opinion that the latter is of the greater importance, and, further, because I believe that if asepsis is adequately and amply practised there will be little necessity for the use of antiseptics in and about the parturient woman. My formula then would be: A rigid employment of asepsis prior to delivery, and an equally rigid employment of antisepsis subsequent to delivery, *provided*, there arise symptoms that render the latter necessary. If a rigid use of aseptic measures be made during the latter days of pregnancy, and during delivery, there will be little occasion, in a normal labor, to employ antisepsis afterward. Abnormal labors are outside of all rules, and each one must be managed according to its own necessities, not only with reference to essential details, but with reference to the minute and technical administration of antiseptic measures. For instance, in a normal labor there will be no occasion for the employment of vaginal lavements for forty-eight hours subsequently to delivery; whereas, in an abnormal labor it may not only be necessary to employ the vaginal douche immediately, but prompt intrauterine irrigation may be absolutely essential.

As a final thought, permit me to observe that with greater care given by the general practitioner in the remote portions of the country and away from the large centers, as well as in the populous cities, it is it is my opinion that so-called puerperal fever may be eliminated as a factor of constant menace in the parturient chamber, and that ophthalmia neonatorum may be absolutely and entirely prevented.

The mortality from pulmonary tuberculosis in a single year, in this country, is declared to be, in round numbers, 100,000. I have no doubt that if statistics could be collated on the subject it would be found that the mortality from childbed is considerably beyond that number; and, further, that a very large proportion of this mortality comes within the line of prevention.

284 FRANKLIN STREET.

VISCERAL PHLEBOTOMY.[1]

BY GEORGE HARLEY, M.D., F.R.S.,
OF LONDON, ENG.,
CORRESPONDING MEMBER OF THE ROYAL ACADEMY OF SCIENCES OF BAVARIA; OF THE ROYAL ACADEMY OF SCIENCES OF MADRID; VICE-PRESIDENT OF THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY OF LONDON, ETC.

Pari passu with the recent advances made in scientific physiology and pathology have most marked changes and improvements taken place in the medical and surgical treatment of disease. Some of these have appeared startling by reason of their novelty; others have intimidated on account of their seeming temerity; many have been stigmatized as chimerical, while not a few have been actually condemned as being beyond the pale of rational therapeutics. Nevertheless, on better acquaintance, most of these have been found to be as replete with wisdom as they have proved to be pregnant with advantage to the healing art. Visceral phlebotomy, of which I am about to speak, may not untruthfully be said to belong to the latter class, for when it was first introduced by me to the profession in 1886,[2] in the form of hepatic phlebotomy, it was not only abused as a most dangerous, but stigmatized as a most unjustifiable operative procedure. Nevertheless, although only six years have glided away since its death-knell was so vociferously sounded, instead of having been consigned to an oblivious tomb, it is not only still alive and flourishing, but it has added to it a twin sister in the shape of pulmonary phlebotomy, by Dr. Christian Simpson; and now I am about to advocate the extension of this mode of curative procedure to every other accessible visceral organ of the body.

[1] Read in the Section of Surgery and Anatomy of the American Medical Association, at Detroit, June 9, 1892.

[2] "Hepatic Phlebotomy," Brit. Med. Journ., November 18; ibid., January 15, 1887.

Thinking that no simpler or more effective plan of proving either the safety of, or the benefits to be derived from any novel system of treatment can be adduced than by quoting successful illustrative cases, I will not waste time in exposition, but at once briefly narrate two most successful examples, which can neither be gainsaid nor doubted; and, in order to save space, and yet to put it in the power of those specially interested in the subject to obtain possession of the details in each case, I will cite cases that have elsewhere been published *in extenso*, the one by myself,[1] the other by my son, Dr. Vaughan Harley:

CASE I.—The patient, a lady of intemperate habits, aged thirty-eight, was not operated upon until she was supposed to be in a dying state, from the combined effects of a greatly enlarged, hard, and inflamed liver, complicated with ascites and marked anasarca. After Dr. Dunbar Walker (whose patient she was) had rendered her insensible with the A. C. E.[2] mixture I pierced the upper part of the liver from right to left with an eight-inch long trocar, of the diameter of between Nos. 2 and 3 English catheter. The normal liver being at least ten inches broad in an average-sized woman, and this liver being greatly enlarged—several inches both laterally and perpendicularly—I felt perfectly safe in thrusting the eight-inch trocar up to its very hilt. This was done with the hope that during its penetration it might wound one or more blood-vessels of sufficient caliber to yield a free stream of blood. On withdrawing the end of the canula about an inch or two, blood issued freely, and twenty ounces were abstracted. The skin-wound was then closed with a piece of sticking-plaster, and a bandage applied.

Such was the benefit derived from the operation that from the very next day the downward progress of the case was arrested. The liver decreased in size, and with the aid of tapping, the ascites and anasarca disappeared, and within three months the patient was so well and strong that she could walk a distance of three miles, and she never had a return of the disease.

CASE II is one of an entirely different character, cited with a view of showing, equally forcibly, the value of hepatic phlebotomy in a case of enlarged and inflamed liver—the seat of strumous abscesses.

The patient was a country lad, aged seventeen, whom I was called to see by Dr. Cooper Key and Surgeon Heaven. The liver dulness extended from the right nipple-level down to two inches below the umbilicus, and four to the left of the median line. Phlebotomy was performed while the patient was

[1] Brit. Med. Journ., November 13, 1886.

[2] This is a safer form of anesthetic than chloroform, consisting of one part of absolute alcohol, two parts of chloroform, and three parts of sulphuric ether, proposed by me, and recommended by the committee "On the uses and effects of Chloroform," appointed by the Royal Medico-Chirurgical Society of London, of which I was a member. See the *Transactions* of 1864, p. 341.

under the influence of the A. C. E. mixture; but although the liver was punctured in several places, such was the hardness and compactness of its tissues (on account of the inflammation) that only a very little blood was obtained. Fortunately, however, profuse hemorrhage took place some hours afterward[1] from the wounded liver, through the bile-ducts into the intestines, with the result that within thirty-six hours the liver had diminished in size no less than an inch and a half all round, which made an enormous diminution, and within six days the first abscess had pointed and been emptied. In three days more a second abscess was likewise emptied, and on the thirty-eighth day the patient returned to his home in Lincolnshire, a distance of 120 miles, without a single bad symptom.

The results of these two cases must, I think, convince even the most skeptical, not only of the safety of this operative mode of procedure, but of its utility as a curative agent, for, without it, I have not the slightest hesitation in saying that both of the patients who were subjected to it would have been in their graves within a few days.

I now come to pulmonary phlebotomy, first proposed and practised by Dr. Christian Simpson.[2] This I consider to be the most difficult form of visceral phlebotomy. From the fact that the lungs are contained between the ribs, and constantly contracting and expanding, it is impossible by the application of an external bandage to bring the thoracic parietes into firm contact with the orifice of the wound made in pulmonary tissues so as to effectually close it. Consequently, the closure of the wound in the lung, after the operation, must be effected by the resilience of the pulmonary tissues being sufficient to retain a blood-clot in the channel made by the trocar. In order to favor this, Dr. Simpson adopted the following plan: "After the withdrawal of twelve ounces of blood the canula was held *in situ* with the finger over the end, to allow a clot forming, and then it was slowly withdrawn. . . . The patient was immediately and markedly relieved, both as regards the cerebral (she had been comatose, G. H.) and pulmonary conditions. No effusion took place; there was only trifling hemoptysis, and a suspicion of a small patch of pleurisy, without a rise of temperature." Dr. Simpson employed aspirating needles in his operations, and although they did not prove like mine, successful, this can scarcely be said to have been due to any fault in the operation, but to the diseases complicating the pulmonary congestion for which the phlebotomy was had recourse to, two of the cases being complicated with advanced organic heart-disease, and the other two being cases of equally incurable Bright's disease.

Having thus shown that the apparently heroic method of extracting blood directly from an inflamed internal organ can not only be practised with safety on a favorably-placed gland like the liver, but on one of the most unfavorably-placed organs of the body for the successful performance of the operation, namely, the ever-moving lungs, I think I need scarely dread censure if I boldly recommend the performance of visceral phlebotomy on every suitably-situated internal organ (when it is in a seriously congested condition) in preference to the application of leeches or cupping-glasses to the external parietes over it, seeing that the cutaneous blood-vessels have in no case whatever any direct communication with the internal organs lying beneath them. Consequently, the theory of doing good is but a delusion, and the practice of leeching and cupping but a snare, if done with the intention of directly diminishing the amount of blood circulating through or stagnating in a visceral organ. As the withdrawal of blood from the cutaneous capillaries can only act beneficially in such cases, in so far as it diminishes the entire amount of blood in the body, and seeing that the largest of the internal organs forms but a small proportion of the whole frame, the diminution in its blood-supply can be but an insignificant one; whereas, by my proposed method, as shown in the case of the liver from which twenty ounces of blood were directly withdrawn, and Dr. Simpson's of the lung, in which twelve ounces of blood were equally directly extracted from the organ, as much or as little blood can be removed from the congested parts as the operator thinks needful.

Within the last few days I proposed extracting blood from a tender, greatly enlarged, and inflamed spleen, but was thwarted by the nervous apprehensions of an imperfectly educated coadjutor, from his not knowing that even needles as large as No. 3 catheters can be not only thrust into but can be kept for twenty minutes in the ventricles of the heart of living dogs with perfect impunity. It is knowledge that inspires surgical confidence, and without it no one ought to attempt visceral phlebotomy. For those about to have recourse to it as a curative measure for the first time the following hints may, perhaps, be of service:

1. If it be deemed advisable to render the patient insensible, induce anesthesia of the skin at the point selected for puncture, by the local application of cocaine hydrochlorate.

2. Select the seat of puncture, and give such a direction to the trocar as will insure the point of its entrance into the organ being brought into direct contact with the parietes by the application of

[1] This case was reported in full by my son, Dr. Vaughan Harley, in his paper "On Abscess of the Liver," Brit. Med. Journ., November 23, 1889.

[2] "A New Method of Bleeding in Some Forms of Pulmonary Congestion, with Four Cases."—*Lancet*, November 1, 1890.

pressure to them by a bandage after the completion of the operation, in order that the mouth of the wound in the organ may be thereby readily and effectually closed.

3. Let the trocar or aspirating needles be of the size of a No. 2 or 3 catheter, and sufficiently long to penetrate deeply into the organ operated on, without there being any risk of entirely transfixing it.

4. Let the direction of the instrument be such as to avoid its puncturing any large bloodvessel.

5. When all these points have been attended to it will save the patient pain if the instrument be rapidly and at once thrust into the organ to the full depth it is intended to puncture.

6. If no blood flows, then slowly and by distinct degrees withdraw the canula, in the hope that a sufficiency of blood will ooze from the transfixed capillaries into the canal made in the organ by the instrument, as will yield a free stream, and enough for the required purpose.

7. When the wished-for amount of blood has been obtained, before withdrawing the canula altogether from the organ, but just before it leaves it, in order to obtain a blood-clot-cork to stop up the wound with, place the finger on the mouth of the canula, and keep it there until a clot has had time to form, both in its interior and in the canal made in the organ itself by the instrument.

8. The next point is to get the clot in the canula to break off from that in the canal, so as to leave the latter behind, in order that by its presence there it may prevent any oozing of the blood from the organ after the withdrawal of the instrument. This is best done, I think, by giving a slight twist to the canula at the moment it is felt to leave the organ. And the resilience of the tissues of the organ will cause them to contract sufficiently firmly round the clot within it to prevent its being drawn out along with the canula.

9. All that now remains to be done is to place an inch-sized square piece of adhesive plaster over the seat of the external puncture, and bind a pad over it, with a long flannel bandage sufficiently firm, so as to ensure the internal surface of the parietes being brought into close contact with the orifice of the wound in the organ, the more effectually to prevent the possibility of accidental internal hemorrhage taking place.

All I have to add is that, if I am not very much mistaken, the day is not far distant when the old-fashioned, erroneous, as well as unsatisfactory, mode of withdrawing blood cutaneously will be totally abolished in all cases of inflammation and congestion of internal organs having no circulating connection with the skin, and that the practice of visceral phlebotomy will become the recognized orthodox method of depletion in such cases.

PULMONARY TUBERCULOSIS: ITS DIETETIC AND REGIMINAL MANAGEMENT.[1]

BY EDWARD F. WELLS, M.D.,
OF CHICAGO.

PULMONARY tuberculosis, the greatest enemy of mankind, is not an incurable disease. However, if the unfortunate subject of this affection is to be given an opportunity to escape the fate of the majority, he must be surrounded by the most favorable conditions, and must submit to certain necessary rules and regulations. I deem it an essential preliminary to success that there should be a happy combination of interests and hopes upon the part of both patient and physician. The patient should be candidly informed of the nature of his malady, of its varied and tedious course, of its leading symptoms and complications, of its dangerous character, of the possibility of cure, and of the necessity of exercising to the utmost his powers of patience, hope, and confidence. On the other hand, the physician should have a wide and exact knowledge of medicine in general and of tuberculosis in particular; he must know and believe that the disease is amenable to treatment; he must be kind, considerate, resourceful, hopeful, truthful, and enthusiastic, and, above all other qualities, he must be possessed of the ability to transfer his convictions, hopefulness, and enthusiasm to his patient. That implicit confidence of the patient in his medical attendant may be obtained and retained, week after week, month after month, and year after year, until at last the victory is won, or defeat has been suffered only after every point has been stubbornly contested, requires a profound knowledge of human nature and the highest qualities of the physician.

One of the most striking features of pulmonary tuberculosis is the progressive loss of body-weight. In the presence of advancing local affection, this is so constant as to afford a very accurate index of the progress of the case. Experience has abundantly proved that in a great many cases it is possible to stay the waste of tissues, and even to cause the patient to gain in weight by giving careful attention to diet, and that under these circumstances the pulmonary trouble is held in abeyance and the local lesions have a tendency to heal. This being the case, it is evident that the subject of feeding tuberculous patients is one of prime importance, and worthy of the most careful consideration.

Anorexia and defective powers of assimilation are present in those cases in which the stomach and intestines, including their adnexa, are affected by organic disease. Loss of appetite is also a prominent feature in many cases during the height of a febrile

[1] Presented to the Section of Practice of Medicine of the American Medical Association at Detroit, June, 1892.

attack, and, in a certain proportion of patients, without any obvious cause. However, the rule is, especially in the earlier part of the attack, that the patient has either a good appetite, with moderate capabilities of assimilation, or he can receive, digest, and assimilate liberal quantities of food, although he may have no desire for it—there being a state of apathy, rather than one of disinclination. It is in this last and largest class that we are able to utilize our knowledge of dietetics to the greatest advantage, and that this paper may not be unduly extended, my remarks will be confined, in the main, to this class of cases.

Foods that contain nourishment in the most concentrated form should constitute the basis of dietetic management. In order, however, that the best results may be obtained, these must be accompanied by properly selected adjuvants, correctives, and—padding. By the last term I mean certain bulky articles of diet that have but little nutritive value, but are necessary for the greatest digestive and assimilative activity.

For many years I have discussed this subject very freely with my patients, inquiring into their preferences and sensations, and obtaining their opinions and estimates, and the following diet-table is the result of my experience. In practice it is suitably modified to meet the surroundings and other exigencies of the individual case for which it is prescribed.

MENU.

On Rising, 6 A.M.

Hot Milk and Vichy. Hot Meat-broth.
Tea, made with Milk.

Breakfast, 7 A.M.

Rare Steak or Loin-chops. Mutton-chops, with Fat.
Bacon or Ham, with Fat.
Eggs.
Potatoes. Saratoga Chips. Fried Mush.
Toast, with Cream or Butter.
Oatmeal, Wheaten Grits or Rice, with Cream.
Fruit.
Coffee or Cocoa, made with Rich Milk.

Lunch, 10 A.M.

Milk. Eggnog. Meat-broth.
Stale Bread. Crackers. Zwieback.

Dinner, 12.30 P.M.

Beef, Mutton, or Chicken-broth. Oyster or Turtle-soup.
Raw Oysters. Fish. Raw Clams.
Poultry. Roast Beef or Mutton. Game.
Potatoes. Beans. Green Peas. Asparagus. Spinach.
Tomatoes. Celery. Pickles. Lettuce. Cauliflower.
Stale Bread. Graham Bread. Corn Bread.
Fruits, with Cream.
Custards. Pie. Cakes.
Milk. Milk Coffee.

Lunch, 3.30 P.M.

Milk. Koumyss. Clabber.
Ham or Tongue Sandwich.

Supper, 6.30 P.M.

Thick Meat or Fish Soup.
Cold Meats. Meat Salads.
Stale Bread. Crackers. Graham Bread.
Meat Jellies. Neufchatel or Cottage Cheese. Fruit Jellies.
Fruit. Cakes. Ice-cream.
Milk Coffee. Eggnog. Milk Tea.

Lunch, 9.30 P.M.

Hot Milk. Clam Bouillon. Beef Tea.

To this list may be added such other foods and drinks as the appetite craves and that are found to agree. Any article of diet that the experience of the patient has shown to be detrimental is to be omitted.

Food should be taken in as large quantity as possible. At each lunch from a half-pint to a pint of liquids should be ingested, and at each of the three principal meals an equal quantity of milk, or of coffee, tea, or cocoa, made with rich milk and cream, should be taken.

There is no objection to changing the dinner hour to 6.30 P.M., and taking a mid-day luncheon equivalent to the supper, as prescribed. Meals should never be hurriedly taken, and they should be always accompanied by cheerful conversation. Eating should be made one of the principal objects of the patient's life.

The diet should be varied to meet special indications or the patient's desires. If there is little or no fever, and if starch, sugar, and fats are well borne, foods containing these principles in abundance should be freely employed. If there is much fever, or if there is apathy or antipathy to eating, the diet should be composed mainly of animal foods and very concentrated nourishment, with fresh fruits and vegetables.

If there is a tendency to flatulent distention of the stomach or bowels after eating, bread and other farinaceous articles of food should be taken sparingly. If the bowels become constipated, fruits, coarse vegetables, corn or Graham bread should be largely eaten; and if diarrhea supervenes, food of this kind should be avoided.

At the very beginning of treatment the patient should be impressed with the great importance of certain hygienic and regiminal regulations. These should be fully discussed with him, and he should be made to understand the reasonableness of the rules prescribed, in order that his hearty and intelligent coöperation may be secured. The peculiarities of the patient must be fully weighed, but the following points I consider with every patient.

Tuberculous patients are usually persons that have formed strong attachments to home, family, and friends, and do not readily adapt themselves to changed surroundings. For this reason, home is the best place for the vast majority of them. This statement does not apply to the comparatively small

contingent of tuberculous patients that are always in touch with their surroundings and who are natural travellers. With these, travel, change of scene, and climatic treatment may be considered, but a change of residence should not be undertaken without thoughtful consideration and the special advice of the medical attendant.

The residence should be exposed to sunshine and be sheltered from raw and cold winds. The rooms should be well ventilated, free from draughts, and comfortably warmed and furnished. The home should be entertaining, pleasant, and cheerful. The patient should sleep alone.

Pleasurable exercise, such as riding, boating, walking, travelling, games, etc., and non-exhausting, useful employment that interests and does not expose to deleterious influences are beneficial.

At frequent intervals the patient should practise forced breathing—both inspiration and expiration. As a measure of the aërial capacity of the lungs he should count aloud as many times as possible without taking breath.

The clothing should be light and comfortable. That next the skin should be of wool and of fine texture. In cold weather, the clothing should be sufficient to prevent chilliness, and the chest should have extra protection.

Once or twice weekly the patient should have a hot sponge or tub bath. The surface should be quickly dried, rubbed to a glow, and enveloped in warm woollen garments. The bath-room should be comfortably heated.

Should night-sweating supervene, the surface should be bathed with very hot water or vinegar, and after being dried should be rubbed with flour, starch, or other absorbent powder.

Twice a day there should be applied to the surface of the chest a stimulating liniment, composed of equal parts of turpentine and oil of hyoscyamus, or oil of sassafras. Mustard plasters and hot applications may be employed for the relief of local pains. These failing to give relief, small blisters may be used.

The cough should be restrained as much as possible, and endeavors to expectorate should be made with every effort. A dry, irritable cough, without expectoration, should be held in check by proper remedies.

The sputa should be received in a cup containing a quantity of moist absorbent and antiseptic material. The contents should be removed once or twice daily, and the cup cleansed. Moist antiseptic cloths may be substituted for the cup. The cloths and contents of the cup should be burned.

Catarrhal colds should be avoided by every known means, and if they occur they should be treated with the utmost care, and the treatment be continued until the disappearance of every trace of catarrh. The patient should consult his physician at once upon the appearance of new symptoms the significance of which may be unknown to him.

The patient should observe and record carefully, upon suitable blanks, his condition from day to day. Such records afford information of the greatest value in formulating prognoses and lines of treatment. He should bring them with him when he consults his physician. "With careful instruction an intelligent patient may become," to a limited extent, "his own observer, and to a certain extent, his own medical attendant," and to his advantage.

163 STATE STREET.

CLINICAL MEMORANDA.

A CASE OF PUERPERAL MANIA.[1]

BY LLEWELLYN ELIOT, MD.,
OF WASHINGTON, D. C.

THE terms "puerperal insanity," "puerperal mania," and "melancholia of lactation" are misnomers; "insanitas in puerpero," "mania in puerpero," and "melancholia ex lactatio" are the terms that should be substituted, since they do not differ clinically from insanity, mania, and melancholia as usually observed; the puerperal state simply precipitates them, either through heredity or mental worry before confinement; or untimely suppression of the lochial discharge or excessive lactation after delivery. More cases of melancholia than of mania are met with in practice. Asthenia favors melancholia.

Without entering into the discussion of the pathology or treatment of mania in puerpero I will submit the history of a case, the notes of which were furnished me by Dr. A. Behrend, of this city, with whom I was associated in the case from the night of the delivery.

I have not been able to find clinical reports of fatal cases of mania in puerpero, and for that reason desire to put the following history on record, hoping to see, in the future, reports of cases both successfully and unsuccessfully treated, so that rational conclusions may be formed upon the subject. Successfully treated cases only are reported, but they throw no light upon prognosis.

Mrs. X., white, thirty-one years old, of good physical development, was delivered of her sixth child on the morning of June 7th.

In her previous confinements, three male children, shoulder-presentations, were born still; one female child was born alive by version; of the fifth pregnancy no history was obtained. Each confinement was attended with hemorrhage, uterine inertia, and fever.

There was a history of hereditary predisposition to insanity on her maternal side, one aunt being at the time of this confinement an inmate of an insane asylum.

On June 2d, Mrs. X. experienced the false pains of labor, and became very apprehensive and despondent as to the termination of her gestation.

On the afternoon of June 5th, after a severe fit of

[1] Presented to the Section of Obstetrics and Diseases of Women of the American Medical Association, at Detroit, June, 1892.

coughing, the membranes ruptured and the waters were discharged; she experienced no pains; dilatation of the os was hardly perceptible; the uterus was high; no certain diagnosis of the presentation was made. Five grains of quinine sulphate were given twice daily, to stimulate the uterus to action.

On June 6th, the patient was very nervous; the uterus was somewhat lower; there were slight pains. A diagnosis of left shoulder presentation was made. During the day the pains became stronger and the patient more nervous. At twelve o'clock at night the os was well dilated, the shoulder presenting, the patient restless and tossing. Version was determined upon. It was at this time that my connection with the case began. At 1.30 an anesthetic was administered; version was performed, and delivery was completed in about half an hour. The child, a male, was born with a knot in the placental extremity of the funis; the heart-pulsations were weak; it could not be resuscitated. Hour-glass contraction followed delivery. The hand was introduced and the placenta extracted; hemorrhage was not profuse; shock was slight. A dram of the fluid extract of ergot and a fourth of a grain of morphine sulphate were administered. During the administration of the anesthetic the woman became almost unmanageable. As soon as the delivery was completed, she evinced symptoms of religious mania, but became quiet under the morphine given.

On June 7th, at 10 A.M., the temperature was 98.6°; the pulse, 90. The woman had rested well; the discharges were moderate; urine had been passed; there was no abdominal tenderness. A light diet was directed.

On June 8th, at 10 A.M., the temperature was 100°; the pulse, 98. There was slight abdominal pain and severe pain in the left thigh. Turpentine was applied to the abdomen and flaxseed poultices to the thigh; belladonna, morphine, and quinine were given every two hours, and the light diet continued.

On June 9th, at 10 A.M., the temperature was 100.5°; the pulse, 106. There was no pain, but much sweating, without chill; the bowels were moved with a saline; quinine sulphate, gr. v, was given every three hours; the lochia were suppressed.

On June 11th, at 10 A.M., the temperature was 100.5°; the pulse, 100. There was slight rambling and irrational action. At 1 P.M. the woman became maniacal, jumping from the bed and attempting to reach the front window. She was with difficulty restrained. The temperature was 100.5°; the pulse, 100. Chloral hydrate and potassium of bromide, each gr. xv, were given every three hours. At 8 P.M. the patient had not slept; she passed urine and feces in bed. Chloral and bromide were continued.

On June 12th, at 11 A.M., the temperature was 100°; the pulse, 110. The mania continued; the bowels were opened with calomel, soda and rhubarb; chloral and bromide were continued. At 8 P.M. the temperature was 100.4°; the pulse was not noted. The condition continued unchanged.

On June 13th, at 9.10 A.M., the temperature was 100.6°; the pulse, 110. The patient presented delirium of an hysterical type; there was no tenderness over the abdomen, but considerable tympanites; the lochia had ceased; feces and urine were discharged involuntarily in bed: turpentine stupes were applied to the abdomen. At 8 P.M. the temperature was 99.8°; the pulse, 100. The condition was unchanged.

On June 14th, at 10.30 A.M., the temperature was 100.6°; the pulse, 110. There was no abdominal tenderness; the tympanites had diminished; there was a slight discharge of blood from the uterus, having no odor; the mania continued; elixir of ammonium valerianate and potassium bromide were ordered. At 1.30 P.M. the temperature was 101.8°; the pulse, 120. The condition remained unchanged. At 9 P.M. the temperature was 99.8°; the pulse, 100. The patient urinated very frequently, but in small quantity.

On June 15th, at 11 A.M., the temperature was 100.5°; the pulse, 110. The tympanites was diminishing; the mania was constant. At 9 P.M. the temperature was 98.6°; the pulse, 110. The condition was not changed; the treatment was continued. The patient refused nourishment.

On June 16th we were unable to take the temperature or the pulse during the entire day on account of the mania. The medicines were continued; nourishment was refused. At 9 P.M. morphine sulphate, gr. ¼, and atropia sulphate, gr. $\frac{1}{150}$, were given hypodermatically; the patient slept until 4 o'clock A.M.

On June 17th, at 10 A.M., the temperature was 104°; the pulse, 119. The mania was constant; the medicines were continued; the patient refused all nourishment. At 10 P.M. the temperature was not taken. The mania was furious. Morphine sulphate, gr. ⅓, was given hypodermatically. The woman slept until midnight, when there was a sudden explosion (physometra), with a great rush of water, followed by a slight, bloody discharge. The abdomen became perfectly flat, the delirium more intense, and nourishment was refused. This physometra explained entirely the cause of the tympanites, showing a continued condition of inertia of the uterus, which appeared at the beginning of labor, and was not owing to any septic condition.

On June 18th, at 10 A.M., the temperature was 104°; the pulse, 120. There was no abdominal tenderness; the patient took nourishment; she rambled constantly, but was more controllable; she took nourishment; the lochial discharge continued; bromide and valerian and quinine sulphate, gr. x, were given. At 1 P.M. the temperature was 103°; the pulse, 116. The quinine was repeated. At 3 P.M. the temperature was 101°; the pulse, 110. Quinine was repeated. At 10 P.M. the temperature was 101; the pulse, 100. The woman was now resting quietly.

On June 19th, at 2 A.M., the temperature was 103°; the pulse, 110. Nourishment was refused. At 7 A.M. the temperature was 104.2°; the pulse, 124. Milk and quinine sulphate were given per rectum. At 11 A.M. the temperature was 103.4°; the pulse, 110. There was entire apathy to everything; asafetida and quinine were given by suppository every two hours; there was inability to swallow; an almost incredible amount of urine was removed with the catheter; no albumin was found. At 10 P.M. the temperature was 104.8°; the pulse, 130. An ice-bag was applied to the head; the urine was removed by catheter; the patient was sponged with alcohol; the pupils reacted to light; nourishment was refused; the lochial flow continued moderate; hyoscyamine, gr. $\frac{1}{100}$, was administered.

On June 20th, at 2 A.M., the temperature was 102°; the pulse, 120. The woman's condition was unchanged. At 11 A.M. the temperature was 104°; the pulse, 126. At 2 P.M. the temperature was 104°; the pulse, 130. Salol and bismuth subnitrate were given for diarrhea; a little nourishment was taken; milk-punch was given every two hours. At 10 P.M. the ice-bag had been continued throughout the day at intervals; the patient took notice and answered questions intelligently.

On June 21st, at 10 A.M., the temperature was 102°; the pulse, 120. The woman's condition was improved; she took nourishment; she rambled at intervals. At 8 P.M. she suddenly collapsed and could not be revived, and died at 9 P.M. of exhaustion.

No autopsy was allowed.

1106 P STREET N. W., JUNE 3, 1892.

VOMITING INDUCED BY AN ELONGATED UVULA; OPERATION; RELIEF.

BY EDWARD F. PARKER, M.D.,
DEMONSTRATOR OF ANATOMY, MEDICAL COLLEGE OF SOUTH CAROLINA, CHARLESTON, S. C.

VOMITING, as a symptom of some disturbance of the digestive canal, is so commonly associated with disease or functional derangement of the stomach and intestines, that we are likely to overlook the fact that the upper part of the alimentary tract is sometimes responsible for the difficulty. A common division of the causes of vomiting is into local, central, and reflex. In the pharynx and surrounding parts, from their exposed position and anatomic relations, we frequently find the origin and explanation of this last class.

Quite recently a case presented itself exemplifying this fact, and while impressing upon me the old medical axiom that to treat disease successfully we must find its cause and remove it, at the same time it illustrated the truth that seemingly grave conditions may arise from trifling causes, which if not discovered and removed, render all treatment useless and ineffectual.

The pharynx and adjacent parts can always be easily and quickly examined, and such examination should be made, so that we may consider or eliminate them as factors in all disturbances that may possibly originate there. In justification of these remarks the following case is interesting and instructive.

During the month of March, 1892, F. G., twenty-one years old, consulted me for nausea and persistent vomiting. His face wore an anxious expression, though he was apparently in good health. The nausea had been annoying him for some time, but the vomiting had only commenced two weeks before. He was scarcely able to retain anything on his stomach. His health had previously been excellent. Medication had failed to give him any relief. I was struck by the man's face.

A month or so previously, in examining the throat of a patient, I found an elongated uvula. I advised an operation and appointed an hour for the next day. The patient was alarmed at the idea of any cutting, and did not return. Now, though this patient did not complain of any symptoms referable to his throat, I thought I recognized in him my former renegade. This identity, however, he denied; but curiously enough, on examining the throat, an extremely long uvula was found, resting on the base of the tongue and exciting retching with every attempt to swallow. The uvula was unusually elongated and tapering in shape, though not equal in length to one described by Morell Mackenzie, that was so long that it was inhaled into the larynx and produced symptoms of suffocation.

Under cocaine anesthesia a piece more than an inch in length was removed, and the next morning the patient returned relieved.

The terms excision and amputation as applied to this operation seem to me to be inappropriate and misleading, as they imply removal of the organ *in toto*, while uvulatome and uvulotomy accurately express the instrument and the operation.

Elongation of the uvula, though more frequently the result of a chronic inflammatory condition of the pharynx and naso-pharynx, which by causing constant hawking and coughing leads to lengthening of the organ and relaxation of the soft palate, may also be congenital.

In the majority of cases our attention is called to the throat by a tickling, irritating sensation, as if a foreign body was present; nausea and vomiting are not so common as symptoms of this condition.

The patient was a good singer and his voice was materially improved by the operation.

It is in the light of a practical lesson, rather than as an unusual or curious incident, that I think this case worthy of report, in that it teaches the necessity of making a thorough examination in every case that comes for treatment, and warns against any routine in prescribing drugs for symptoms that may owe their origin to many different causes.

70 HASELL STREET.

BACKWARD DISLOCATION OF THE HEAD OF THE RADIUS.

BY ALBERT C. BARNES, A.B., M.D.,
RESIDENT PHYSICIAN TO THE POLYCLINIC HOSPITAL, PHILADELPHIA.

BACKWARD dislocation of the head of the radius is a very rare occurrence, Markoe, quoted by Agnew, having been able to collect records of but twenty-eight cases. The following presented so many characteristic symptoms as to make the correctness of the diagnosis indisputable:

W. C., six years old, fell with considerable force, and in an effort to protect his trunk from injury suddenly threw out his right arm, so that the violence came directly in contact with the palm of his hand, while his arm was in an extended and extremely pronated position—a similar history, it will be observed, to that of most cases of "Colles's fracture." Ten minutes after the accident the boy was brought into the hospital, and presented the following deformity: His arm, in a position of almost complete pronation, was flexed at an angle of about 120°; his hand was also somewhat flexed and fixed. An examination of his elbow-joint, the normal contour of which was but slightly disturbed, revealed behind the external condyle a hard, resisting mass, to which a distinct rotary movement could be communicated by force applied to the distal extremity of the radius. To prove that this mass was the displaced head of the radius, we searched in the position in which the head of the radius normally lies, and detected there a

slight depression corresponding with the position of the sigmoid fossa. Careful and repeated manipulation failed to elicit crepitus—thus excluding fracture of the internal condyle—a complication that frequently exists in conjunction with backward dislocation of the radius. Attempts at flexion, extension, pronation, and supination were attended with excruciating pain—a fact that would seem to indicate laceration of the capsular ligament. The treatment was very simple. The patient being etherized, counter-extension was applied to the arm, with extension of the forearm and direct pressure on the dislocated head of the bone. The latter readily slipped into its normal position. The joint was then enveloped in gauze saturated with lead-water and laudanum, an anterior extreme obtuse-angled splint applied, and the arm dressed in supination. Subsequent daily dressings show that the bone is still in position. The result thus far indicates perfect recovery, with preservation of the integrity of motion.

MEDICAL PROGRESS.

A Successful Laryngectomy.—At a meeting of the Philadelphia County Medical Society, J. SOLIS-COHEN presented a patient, forty-four years old, from whom he had removed the larynx and the first ring of the trachea. Nineteen years previously the man had presented symptoms of laryngeal obstruction and a large papilloma was removed piecemeal by intra-laryngeal procedures. For ten years there was no indication of recurrence. Then the previous symptoms returned, and various modes of treatment were employed. For a year the symptoms had been aggravated. A growth occupied a large portion of the left side of the larynx, almost occluding its lumen. It had penetrated the walls of the larynx and projected externally. Precautionary tracheotomy was performed, and three or four weeks later a portion of the growth was removed by intra-laryngeal procedures. The external growth was subsequently excised, the larynx split, and all the internal growth removed. The case did well for four weeks, when recurrence took place, the neoplasm growing rapidly. Radical operation was now proposed and acquiesced in. The entire larynx and the first ring of the trachea were removed. The esophagus was left as nearly intact as possible. The patient made an uninterrupted recovery.

Suppurative Otitis Media in Consequence of a Carious Tooth.—SCHWARTZ (*Zeitschr. für Ohrenheilk.*, 1892, xxii, 2, p. 121) has reported the case of a man, twenty-one years old, who complained of pain in the ear, with a purulent discharge. There was some swelling of the bony portion of the auditory canal. The employment of the Eustachian catheter was attended with bleeding from the nose. Examination of the nasal cavity disclosed the presence of the carious root of the second molar tooth on the left side of the upper jaw and a fistula traversing the hard palate. The tooth was removed and the fistula closed. Evidences of inflammation of the mastoid process, however, became prominent, and it became necessary to operate. When the mastoid process was opened, granulations and pus were found. These were removed and suitable dressings applied. There were no further complications, and the case progressed to perfect recovery.

The Reflexes in Spinal Injuries.—From an analysis of twenty-nine cases of injuries to the cervical and dorsal regions of the spinal cord under his observation, THORBURN (*Medical Chronicle*, 1892, xvi, 2, p. 73) concludes that in total transverse lesions of the spinal cord both the superficial and the deep reflexes below the functional level of the injury are permanently and entirely abolished, while in partial lesions the reflexes are retained, perhaps exaggerated. It is thought that the abolition of the reflexes is dependent upon isolation of the spinal centers from their cerebral connections. It is further concluded that shock is not the cause of the early loss of the reflexes in spinal injuries. If the lesion causes complete paralysis and anesthesia, the deep reflexes are always lost. If motility or sensibility, or both, return, the reflexes likewise return. The rectum and bladder participate in the derangement of the reflexes.

Cachexia Strumipriva, with Paralysis of the Right Vocal Band.—NATIER (*Rev. de Laryngol., d'Otol., et de Rhinol.*, 1892, No. 12, p. 422) has reported the case of a man, twenty-nine years old, in which thyroidectomy had been performed for the removal of a goiter. The man appeared to be puffed, the eyes fixed and small, the cheeks relaxed, and the face expressionless. The skin was dry and colorless; the hairs were likewise dry and brittle, and had lost their luster. The pulse was small and slow. There was increased emotional mobility. On laryngoscopic examination the right vocal band was found immobile and in the median position, while the movements of the left band were paretic.

A Vegetable Substitute for Decalcified Bone Plates.—BARACZ (*Centralbl. für Chirurgie*, 1892, No. 23, p. 481) proposes the employment of plates obtained from vegetables as a substitute for decalcified bone plates in the various anastomotic operations upon the digestive canal. By experiments upon animals he has found that plates prepared from Spanish turnips answer the purpose admirably. Such plates have the advantages of being elastic, mobile, and absorbable. The suggestion has found practical application in a case in which gastroënterostomy became necessary by reason of the existence of inoperable carcinoma of the pylorus and stomach.

Double Optic Neuritis Following Influenza.—SNELL (*Brit. Med. Journal*, No. 1642, p. 1308) has reported the cases of two females, nineteen and thirteen and a half years old, respectively, in each of which failure of vision was noticed a few weeks after an attack of influenza. In the elder girl the neuritis had nearly passed off. When she first came under observation the optic discs were atrophied, and there was no perception of light. The younger patient was seen three weeks after vision began to fail; the neuritis was then well marked. The inflammation had subsided, but the discs were atrophic, and there had been but little improvement in sight.

The Urine in Epilepsy.—At the recent French Surgical Congress GILLES DE LA TOURETTE (*La Médecine Moderne*, 1892, No. 18, p. 284) announced that the differentiation of focal epilepsy of hysterical origin from focal

epilepsy of organic origin could be made by examination of the urine. Observation has shown that after a paroxysm of epilepsy of organic origin the proportions of fixed residue, of urea and of phosphates, are increased beyond the normal, while after an attack of epilepsy of hysterical origin these proportions are diminished below normal.

The Treatment of Leg-Ulcers. — At a meeting of the Philadelphia County Medical Society T. S. K. MORTON recommended the following treatment of leg-ulcers: The surroundings are thoroughly cleansed with soap, brush, and water, and, if necessary, shaved. Then a douche of simple water is applied, followed by one of sublimate solution (1 : 1000), if the ulcer is foul, inflamed, or otherwise contaminated. Next, a spray of hydrogen dioxide (15-volume solution) is employed. When active effervescence has ceased, the surface is gently irrigated with simple water. The ulcerated area is then covered with strips of protective. A dressing of gauze or butter-cloth wrung out of sublimate solution is next applied; over this the bandage, without reverses. The treatment should be repeated daily, or on alternate days, until the wound presents a healthy appearance, and then with diminishing frequency.

Hydrocephalus of Syphilitic Origin.—HELLER (*Deutsche medicin. Wochenschr.*, 1892, No. 26, p. 608) has collected from the literature sixteen cases of hydrocephalus, in which a history of syphilis could be definitely traced, and adds a case under his own observation. He, therefore, issues the injunction that, in every case of hereditary syphilis the possibility of the development of hydrocephalus should be borne in mind, and that, in every case of hydrocephalus, a history of hereditary syphilis should be inquired for. If a diagnosis of hereditary syphilis is at all probable, energetic antisyphilitic treatment is at once to be instituted.

The Pathogenesis of Eclampsia.—From a careful study of two fatal cases of eclampsia GERDES (*Deutsche medicin. Wochenschr.*, 1892, No. 26, p. 603) arrives at the conclusion that the disease is dependent upon the activity of a specific bacillus, infection occurring by way of the uterus, probably in consequence of an endometritis antedating conception. Convulsions occurring during parturition, dependent upon eclampsia, present distinctive pathologic features. Anatomically, eclampsia is a well-defined and well-characterized disease. The profound organic changes found in cases of eclampsia cannot be fully explained by the mere presence of a bacillus. They probably result, directly or indirectly, in consequence of the action of a toxine.

Epilepsy Cured by Replacement of an Anteflexed Uterus.—SNYDER (*The Physician and Surgeon*, July, 1892, p. 305) reports the case of a girl, nineteen years old, who had had nocturnal epileptic attacks for six years, with dysmenorrhea, setting in shortly after the beginning of menstruation. Examination disclosed the existence of pronounced anteflexion of the uterus and a small cervical canal. After dilatation and straightening of the cervical canal, menstruation became normal and the attacks did not again occur.

Sarcoma of the Buttock Treated by Ligature of the Internal Iliac Artery.—At a meeting of the Clinical Society of London, TREVES (*Lancet*, 1892, 3588, p. 1244) reported the case of a lad, eighteen years old, who presented a sarcoma of the buttock of at least three months' duration, for the relief of which the internal iliac artery was ligated by the intra-peritoneal method. Remarkable shrinking of the growth took place, and the lameness and intense pain that had been present disappeared. The patient remained able to walk for ten months after the operation, but died at the expiration of fourteen months.

Intra-urethral Chancre.—BERG (*Monatshefte für prakt. Dermatologie*, 1892, XV, 1, p. 14) has reported the case of a man with gonorrhea, in which, a discharge persisting, examination disclosed the presence, within the urethra about an inch from the meatus, of a chancre. The accuracy of the diagnosis was confirmed by the development of secondary manifestations, which yielded to the employment of mercurial inunctions.

Immunity to Tetanus. — BRIEGER and EHRLICH (*Deutsche medicin. Wochenschr.*, 1892, No. 18, p. 393) have experimentally demonstrated that the milk of animals rendered immune to tetanus contains substances capable of conferring immunity.

TIZZONI and CATTANI (*Deutsche medicin. Wochenschr.*, 1892, No. 18, p. 394) have found that immunity to tetanus exists in the offspring of rabbits and rats that have been rendered immune to tetanus.

The Saliva and Pathogenic Micro-organisms.—A study of the saliva by SANARELLI (*Centralbl. f. Bakt.*, 1892, No. 25) has demonstrated that the saliva is an unfavorable medium for many pathogenic microörganisms. The bacillus of diphtheria may survive for some time, but finally succumbs. The saliva is an excellent medium for the diplococcus pneumoniæ, which grows rapidly, but loses its virulence.—*Monats. f. prakt. Derm.*, 1892, No. 11, p. 483.

The Influence of Antirabic Inoculation upon Epilepsy.—Two epileptic children, bitten by rabid dogs, were treated at the Pasteur Institute at Paris by antirabic inoculations. Not only did rabies not develop, but the epileptic seizures subsequently failed to appear. A similar procedure was adopted in the case of a two-year-old child with extensive cicatrices of the face from burns received two years previously. Two attacks occurred in the course of the treatment, but none afterward.—*Wiener medicin. Presse*, 1892, No. 24.

Recurrent Cerebral Tumor, with Two Operations.—ERB (*Wiener medicinische Presse*, 1892, No. 24, p. 980) has reported the case of a man, forty-seven years old, who presented symptoms of a tumor of the right central convolutions, for which he was operated on, and the growth, a glio-sarcoma, removed. Eight months later the symptoms had returned, and a second operation was performed. The growth was found larger than before. The result was not quite as satisfactory as after the first operation.

Chorea Nephritis. — THOMAS (*Wiener medicinische Presse*, 1892, No. 24, p. 980) has reported the case of a

boy, fourteen years old, with chorea, who likewise presented febrile symptoms, while the urine contained albumin and tube-casts. There was also some edema of the lower extremities. In the course of several days the albumin disappeared from the urine and the choreic movements ceased.

THERAPEUTIC NOTES.

Specific Treatment of Pneumonia.—NEISSER (*Deutsche medicin. Wochenschr.*, 1892, No. 25, p. 593) has reported three cases of pneumonia treated by means of injections of blood-serum. The first patient was seen on the third day of his illness. The lower lobe of the left lung was infiltrated and the sputum contained virulent diplobacilli. An injection of 130 c.cm. of serum obtained from a pneumonic patient two days after the crisis had occurred was made into a vein of the arm. The temperature at once began to decline, the pulse to diminish in frequency, copious perspiration occurred, and convalescence was uninterrupted. The second patient was seen on the fourth day and presented infiltration of the left lung posteriorly. An injection of 70 c.cm. of serum, obtained from the first patient two days after the crisis, was given. Defervescence soon set in. A week later, a pleural effusion was detected and relieved by puncture. Fifty c.cm. of the fluid thus obtained was used for injection in a patient, who in the course of an attack of influenza was seized with a chill, whose sputum contained virulent diplo-bacilli and who presented other phenomena of pneumonia. The temperature at once subsided, perspiration set in, and improvement manifested itself. The temperature remained above normal and a slight pleural effusion formed, but recovery rapidly ensued.

Chlorphenol is the name given to a volatile combination of chlorine and carbolic acid, which has been employed by Passerini by inhalation in the treatment of tuberculosis, bronchitis, and laryngitis. A bit of absorbent cotton is held before the mouth, and drop after drop of chlorphenol is added. At first, fifteen drops are given. The dose is gradually increased by two or three drops at each inhalation until thirty drops or more are taken at a time. The inhalations ought not be continued for longer than five minutes at a time, and should be repeated at least four times a day, an hour before or two hours after meals.—*Journal de Médecine*, No. 25, p. 301.

Phenocoll Hydrochloride.—From a clinical study, BUMM (*Wiener medizin. Presse*, 1892, Nos. 21 and 22) concludes that phenocoll hydrochloride is an active and almost certain antipyretic in tuberculosis in doses as small as seven and a half grains. In the debilitated and in the last stages of the disease, however, the administration of the drug is to be abstained from. In erysipelas the antipyretic effect is slighter and less constant. The action is greatest at the acme of the fever, or with a falling temperature. The decline of temperature occurs usually two or three hours after administration of the remedy, and is often accompanied by profuse perspiration. The drug proved ineffective as an anti-rheumatic. As an anti-neuralgic it acted well in doses of seven and a half grains in migraine. It failed in myelitis and sciatica. Unpleasant secondary manifestations on the part of the intestinal tract and the heart were exceptional.

Arsenic in Leukemia.—At a meeting of the Clinical Society of London, DREW (*Lancet*, 1892, No. 3588, p. 1244) presented a case of leukemia in a man, in which, in the course of three months of treatment with liquor arsenicalis in gradually increasing doses up to one hundred minims daily, the greatly enlarged spleen became much reduced in size, while the proportion of colorless blood-corpuscles diminished from 1 : 14 red to 1 : 400. The number of red corpuscles was increased, but the proportion of hemoglobin underwent but little change.

Syphilotherapy.—DARZENS (*Rev. de Laryngol., d'Otol. et de Rhinol.*, 1892, No. 13, p. 457) has reported a case of tertiary syphilis that had resisted ordinary measures, but which yielded to the following combination:

℞.—Potassii iodidi }
Ammonii iodidi } . . āā ʒij.
Sodii iodidi }
Hydrarg. iodidi rubri . . gr j.
Aquæ . . . . . gr. xij.—M.

S.—Two tablespoonfuls daily.

The beneficial action of this combination is ascribed to the fact that the ammonium and sodium salts of iodine are more soluble than the potassium salt, in consequence of which the first two are rapidly eliminated, while the last is the longer retained. It is suggested that an analogous explanation applies to the utility of the mixed bromides in the treatment of epilepsy.

For Exophthalmic Goiter.—

℞.—Pulv. ipecac. . . . . gr. ss.
Pulv. digital. fol. . . . gr. ⅓.
Ext. opii. . . . . gr. $\frac{1}{10}$.—M.

Ft. pil.

S.—From four to six in twenty-four hours.

DIEULAFOY, *Journal de Méd. de Paris, No. 25.*

For the Incontinence of Urine of Children.—

℞.—Tinct. belladonnæ }
Tinct. cubebæ } . . āā f ʒv.
Tinct. nucis vomicæ }
Tinct. rhus aromaticæ } . āā f ʒijss.
Tinct. cascarillæ . . . f ʒiv.—M.

S.—Ten drops at bedtime and during the night for a child of from seven to ten.

Journal de Méd. de Paris, No. 24.

For Tinea Versicolor.—

℞.—Acid. salicylic. . . . . gr. xv.
Sulphuris precip. . . . ʒj.
Lanolin }
Vaselin. } . . . . āā ʒiijss.

M. et ft. ung.

S.—Apply topically. HARTZELL.

Thiol is recommended for constipation. A pill of a grain and a half is given daily for ten days.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 23, 1892.

PULMONARY TUBERCULOSIS.

As of such vital importance do we view any additions to our knowledge of pulmonary tuberculosis that, at the risk of proving tiresome, we present herewith a summary of a study of 1000 cases made by R. W. PHILIP (*Edinburgh Medical Journal*, May, 1892, p. 998). Coming from so reliable a source, questions of diagnosis and of observation are not to be raised, and the report must be received as a valuable contribution to the literature of the subject.

The association of pulmonary tuberculosis with insufficiency of fresh air and exercise, with confinement in badly-ventilated and over-heated apartments, with the inhalation of dust, with exposure to irregular fluctuations in temperature, with frequent childbearing and prolonged lactation, was well marked.

The larger number of cases occurred in males—63.7 per cent. As a rule, females came under observation at a later stage of the disease than did males, and the process pursued a more rapid course in the former than in the latter.

The liability to the disease seemed equally great in the married and the unmarried, although a larger number of married (374) than of unmarried (263) males suffered. The latter difference is to be explained by the fact that most of the cases were in working-people, who marry early, as a rule.

Frequent pregnancy and prolonged lactation appeared to be partly responsible for 6.5 per cent. of all the cases in females, and for 18 per cent. of those in married women. In women, amenorrhea was common, while there was a tendency to aggravation of the general symptoms at the menstrual period, hemoptysis especially being common at that time.

The largest number of cases occurred between twenty-five and thirty-five years of age. In males, the maximum was between thirty-five and forty; in females, under thirty. After thirty or thirty-five in the female, and after forty in the male, the chronic type of disease prevailed.

A comparison of the heights of 500 male adults presenting well-marked pulmonary tuberculosis with the heights of 500 male adults presenting various other affections, revealed a close correspondence. In both groups, the greatest number of cases were found in those five feet six inches in height.

The questions of heredity and contagion were studied with great care. In 23.3 per cent. of cases a definite family history of tuberculosis could be traced; in 5 per cent. more, some doubt existed; in 70 per cent. the family history was good, so far as tuberculosis was concerned. "It seems . . . that we may safely limit the influence of heredity . . . to the production in the tissues of a susceptibility to, or at least a diminished power of resisting the tubercle-bacillus." On rigid scrutiny 6.7 per cent. of the cases could be traced to contagion.

In the vast proportion of cases the tuberculous process began at an apex. In 2.3 per cent. only was it exclusively or especially basal. In 40 per cent. the left, and in 34.3 per cent. the right lung was affected alone or in greater degree, while in 25.7 per cent. both seemed equally affected.

In 40 per cent. of cases the patients could assign no cause for their illness; in 12.8 per cent. the disease was attributed to chill; in 12.4 per cent. to bronchitis. In 5.6 per cent. of cases a history of exposure to inhalations of dust was obtained. In 8.2 per cent. of cases the illness was dated from a previous pleurisy. In 8 per cent., patients attributed the commencement of their illness to hemoptysis. In only 5 per cent. was a close sequence of tuberculosis upon croupous pneumonia ascertainable. Of

the cases below fifteen years of age, 30.5 per cent. had a history of recent measles. In 4.4 per cent. the onset of the disease was distinctly traced to an attack of influenza.

In 1 per cent. there was evidence of concurrent syphilis, and in less than 1 per cent. more a likely history of syphilitic infection. In 1 per cent. there was a history of acute rheumatism; manifestations of subacute and chronic forms of rheumatism were not infrequent. In 7 per cent. there was a history of malarial fever. In one case only was diabetes a precedent condition. Alcoholism was clearly traceable in 1.4 per cent. In 10.5 per cent. laryngeal complications were present; in a further 6 per cent. they were suspected.

Mitral valvular incompetency was present in seven cases; mitral obstruction in three cases; mitral incompetency and regurgitation in six; and pulmonary obstruction in four. Only 1.2 per cent. presented glandular involvement; less than 1 per cent., osseous or articular involvement; and less than 1 per cent., cutaneous involvement; 1 per cent. (all males) suffered from *fistula in ano*.

In an analysis of the results of treatment, 469 cases were considered. These were under observation for not less than six months, and the greater number for a longer time. In 117 cases (24.94 per cent.), there was continuous improvement in symptoms, physical signs, and general conditions for a period of not less than six months, a gain of more than five pounds having been maintained. In 163 cases (34.75 per cent.), the improvement was less decided. In 113 cases (24.1 per cent.), the results were indifferent, the patients ultimately growing worse. Seventy-six cases (16.2 per cent.) did badly, progressing to a fatal termination.

While the conclusions arrived at from the foregoing study are largely in accord with those of other observers, some additional light is thrown upon a subject no phase of which can be considered unimportant. Several points, however, deserve special mention.

The significance of hereditary transmission is shown to be a subordinate one, while there can no longer be any doubt of the contagiousness of pulmonary tuberculosis. A recognition of the accuracy of these propositions, particularly of the second, should lead to the adoption of rigid measures calculated to prevent the extension of a disease transmissible by intimate contact and communication. Sick and well should, as much as possible, be kept apart, and ample provision should be made to render innocuous and to prevent the dissemination of the ejecta and dejecta of the infected. Efforts should be directed to overcome the tendency to the disease in a predisposed subject by guarding the general health with jealous care and by raising the nutritive processes to such a standard of perfection as to render the body-tissues resistant to the invasion of noxious agencies. The intelligent physician of today must recognize that tuberculosis is not only a curable disease, but also a preventable one.

The small proportion of cases in which the tuberculosis appeared as a sequence of croupous pneumonia is a noteworthy observation that carries its own lesson. A larger proportion of cases seemed to be related to antecedent pleurisy. One will also be struck by the small number of cases associated with diabetes.

The large number of cases in young persons in which there was a history of recent measles should constitute sufficient admonition for the precautions to be taken in the convalescence from a disease considered to be among the mildest of the commonest. The old notion of the non-concurrence of pulmonary tuberculosis and valvular disease of the heart receives rational modification. Not only was the association relatively infrequent, but in the cases with valvular disease the course of the pulmonary affection was apparently retarded.

Finally, the results of treatment must be considered as in the highest degree encouraging. As the therapeutic procedures employed are not named, it is reasonable to assume that they were those in current use. The report bears the stamp of a healthy conservatism, and is free from any excess of zeal or enthusiasm that might attach to a special mode of treatment; so that the results recorded may be accepted as the unavoidable conclusions of an impartial study.

THE SENSORY CONDUCTION PATHS IN THE SPINAL CORD.

THE views held by most physiologists in regard to the paths that conduct sense-impressions in the cord have been based upon the classical experiments of BROWN-SÉQUARD, who taught that, soon after entrance at the posterior roots, all sensory impulses, save those of muscular sense, underwent complete decussation, passing up the opposite side. Although supported by a certain amount of clinical evidence, this theory has not been allowed to go unchallenged.

An epitome of the literature of the subject, together with the results of some personal experimental work by DR. F. W. MOTT, has been published in the *Philosophical Transactions* of the Royal Society of London for this year.

MOTT, under the direction of PROFESSOR SCHAEFER, experimented on nine monkeys, cutting through one half of the cord at different levels, and studying carefully the clinical and anatomic consequences. By means of a strictly antiseptic technique he was able to avoid the confusion arising from wound-infection, an evil that has too often vitiated the results of other observers. An analysis of his report shows that, after hemisection of the monkey's cord, conscious sensation and the power of localization usually remain on the non-paralyzed but *not on the paralyzed side*. In testing the sensibility, the use of Schiff's "clamp test" was found to be the most satisfactory. The clip was always removed from the non-paralyzed foot, but when attached to the skin of the paralyzed one the blindfolded animal either paid no attention to it or would scratch the same spot on the foot of the opposite side (Allochiria). The knee-jerk on the side of the lesion was generally abolished for a few days; later it was exaggerated. A few hours after the operation, vasomotor paralysis on the side of the section was manifested, the foot becoming swollen, dark, and distinctly hotter than its fellow; this paralysis was always temporary, passing off in one or two weeks. The surface temperature was at first higher on the side of the paralysis.

There was never any marked paralysis of the muscles invariably associated in movement with those of the opposite side. On an average, at the end of three weeks movements of the hip and knee returned on the paralyzed side; they were usually associated movements of flexion and extension. In some of the cases the motor areas of the cortex were exposed after several weeks and the effects of electric stimulation observed. The block was thus shown to exist even after a very complete return of associated movement.

Microscopic examination of the cord revealed the usual secondary degenerations; there were no crossed degenerations—and there had been no regeneration of nerve-fibers at the site of the lesion. MOTT believes that the direct cerebellar tract has its origin in the nerve-processes of the ganglion-cells of Clarke's vesicular column; and with reference to the antero-lateral tract he differs from both GOWERS and EDINGER in thinking that it is made up of fibers coming from cells of the *same* side.

These experiments prove conclusively that in the monkey the sensory paths do not entirely cross, and in addition make it probable that while painful and thermic sensations may pass up either side of the cord, the sensations of touch and pressure associated with localization, as well as the muscular-sense impressions, pass up chiefly by fibers of the same side. The return of sensation on the paralyzed side may be due to the development of collateral channels for sense, just as there are collateral channels formed for the production of bilateral associated movement.

To explain the peculiar condition of allochiria one may think of the nerve-impulse as being conducted, on account of the hemisection, in some way to the opposite side—and, after ascending the cord, crossing again high up to finally reach the cerebral hemisphere of the same side. Such a sensory impression of course misleads the animal as to the foot irritated, and it will keep up its fruitless attempts at removal until undeceived by visual correction.

These researches of MOTT give results quite in accordance with the experiments of WEISS, HOMAN, and OSAWA, who operated on dogs, and confirm the deductions of HORSLEY and GOTCH from their electric methods of examination. Nothing can as yet be definitely said as to the particular tract made use of by a particular variety of sensory impulse. The pathologic histology of tabes has given some support to the view that the muscular-sense fibers pass up in Goll's columns, and the loss of painful and thermic sensations in syringomyelia suggests the gray matter as the conducting medium for these impressions. On the other hand, we know that the gray matter of different levels is connected by certain ascending internuncial fibers—a fact that makes it probable that the central gray mass in itself does not conduct impulses of any kind very far.

The different theories as to the production of hyperesthesia are most conflicting, and no one of the various suggestions (*e. g.*, hyperemia, edema, removal of inhibitory influences) can be regarded as perfectly satisfactory.

The question, How far are we justified in applying the knowledge experimentally gained of the conduction paths in the spinal cord of monkeys to the physiology of the human cord? is a difficult one, which we shall not attempt to discuss. The cases of hemilesion of the cord in human beings that have been thoroughly worked out clinically and

microscopically are unfortunately few in number, and indeed so far as they go give evidence in favor of the decussation of painful sensations soon after their entrance at the posterior roots. They do not, however, point to any similar decussation of the impressions of tactile sense. We can scarcely expect a satisfactory clearing up of the subject until we possess a much more comprehensive series of cases in which the clinical phenomena studied by unbiased observers have been controlled by subsequent systematic histologic examinations.

DIPHTHERIA AND CROUP.

THE science of bacteriology has already opened a floodway of light upon many obscure problems in the etiology of disease; and evidence is not wanting as to the practical application of the information obtained from this source. While perhaps not yet absolutely proved, there is abundant testimony, clinical and otherwise, pointing to the identity of the two processes, diphtheria and croup. Partly in consequence of early teaching, partly because the evidence is not conclusive, there is still a minority that maintains the individuality of the two affections. One of the most conclusive clinical arguments of their identity is afforded by the fact that in some of the large Continental hospitals cases of croup and diphtheria are placed side by side in the same ward, and the cases of croup do not become infected; while it is not rare for diphtheria to develop in a family in which an apparent case of croup has been present.

The almost general acceptance of the dictum of identity is indicated by the tendency to treat cases of croup as though they were diphtheritic, and the instructions of Boards of Health that cases of croup be reported. FRAENKEL (*Deutsche medicin. Wochenschr.*, No. 24, 1892, p. 564) has added an opportune and valuable contribution to the controversy. The opportunity was afforded him of holding autopsies in four cases, clinically typical instances of croup. In none were subjective or objective evidences of pharyngeal involvement present. All presented hoarseness and marked difficulty in breathing. In two, tracheotomy was performed. The autopsies confirmed the freedom of the pharyngeal structures. In one case the membrane was situated below the glottis. Examination of the membrane present in each case disclosed the presence of the bacillus of diphtheria described by KLEBS and LOEFFLER, the identity of which was absolutely assured by its morphologic appearances, by its behavior in culture, and by its pathogenicity to animals. It is true that the number of cases reported is small, but the evidence adduced is positive and conclusive, and not to be controverted by any negative evidence.

Investigations by MIDDELDORPF and GOLDMAN (*Deutsche medicin. Wochenschr.*, No. 24, p. 570) have disclosed the identity of the pathologic processes in croup and diphtheria. In both there occurs an intense inflammation of the mucous membrane, leading to destruction and desquamation of epithelium. Abundant exudation takes place, with subsequent coagulation and the formation of membrane.

CHOLERA IN EUROPE.

CHOLERA once more threatens Europe. According to well-credited accounts it has invaded European Russia, but its presence elsewhere on the Continent has not been verified. While there is apprehension in this country lest the march of this scourge may continue westward, it can hardly be said that the United States is menaced so long as European commercial ports remain free from the disease. Nevertheless it is the part of prudence to look to our defences and to make every preparation to guard against this insidious enemy.

Sanitary officials abroad are on the alert, and strenuous efforts are being made to interpose barriers to the onward march of the disease; but too much dependence should not be placed on this means of protection. Communication is constant and rapid, and an outbreak of the malady in European ports brings it close to our doors. Fortunately, the points of entrance are limited in number, and to them the greatest attention should be paid.

The report that cholerine, which is prevalent in and about Paris, is a mild form of true cholera has been discredited by an official statement received by Surgeon-General WYMAN. Be this as it may, the large number of cases gives rise to a suspicion that dare not be disregarded.

Vigilant inspection of all arriving vessels should be provided for, and ample preparation for detaining for observation all suspected passengers and for disinfecting effectively the clothing and effects of passengers, and for treating thoroughly the vessels, should be made in advance. Weak places in the

line of our quarantine defences should be made strong and past oversights be corrected. A grave responsibility rests upon the sanitary authorities of maritime ports, and to them the country looks for protection.

REVIEWS.

A JUNIOR COURSE OF PRACTICAL ZOÖLOGY. By A. MILNES MARSHALL, M.D., D.Sc., M.A., F.R.S., Professor in the Victoria University; Beyer Professor of Zoölogy in Owens College, Manchester; Late Fellow of St. John's College, Cambridge. Assisted by C. HERBERT HURST, PH.D., Lecturer in the Victoria University; Demonstrator and Assistant Lecturer in Zoölogy in Owens College, Manchester. Third edition. London: Smith, Elder & Co., 1892.

THIS is the third edition of Professor Marshall's work, the first having appeared in December, 1886, and having been compiled for his classes in Owens College, Manchester, England. The work is now, owing to its usefulness, employed as a text-book in many other quarters.

The title of this justly popular work is misleading, inasmuch as, strictly speaking, the volume does not treat of "Practical Zoölogy," but is rather a guide-book to practical zoötomy, or a manual of animal morphology. In plan, it almost exactly follows Huxley's *Practical Biology*, and is even still nearer T. J. Parker's admirable little treatise on *Zoötomy;* but it is more extensive than either, and consequently correspondingly more useful to the practical student in the morphologic laboratory. Although quite brief, the sections in the introduction on the observations of animals during life, drawing, methods of killing animals, dissections, injection, manipulations of the microscope and reagents, and many other useful hints to the anatomist, are very clear and extremely valuable. Chapters beautifully illustrated by means of the finest woodcuts are devoted to the protozoa, the hydra, the liver-fluke, leech, earthworm, mussel, snail, crayfish, cockroach, lancelet, together with appropriate types from the vertebrate series. We fail to see, however, why Professor Marshall took up the study of the fowl and pigeon after the chapter on the rabbit rather than before it. The fact has its disadvantages, and should be remedied in the next edition. Moreover, we would suggest that a chapter on some appropriate reptilian form be added, as well as one devoted to some typical teleosteon fish. Upon the whole, the volume is remarkably free from mistakes of any kind.

DISEASES OF THE NERVOUS SYSTEM. By JEROME K. BAUDUY, M.D., LL.D., Professor of Diseases of the Mind and Nervous System and of Medical Jurisprudence, Missouri Medical College, St. Louis. Second edition. Philadelphia: J. B. Lippincott Company, 1892.

THE first edition of this work appeared in 1876, and has been out of print a number of years. The present treatise is divided into two volumes, the book now under consideration being Vol. I, although, curiously, the title-page does not convey this information. In the preface, however, the author states that diseases of the brain, cord, and peripheral nerves will be considered in the second volume. The volume under review deals with anemia and hyperemia of the brain and inflammations of its membranes, and the various forms of insanity. The subjects are not considered systematically, but are presented in the form of lectures (nineteen in number) delivered to the students of the Missouri Medical College. The work will doubtless have its widest circulation among Dr. Bauduy's pupils. We cannot help thinking that its influence will be limited, for it sadly lacks the stamp of originality. Many prominent alienists and neurologists are freely quoted. Indeed, whole pages are, at times, presented between quotation marks. Not infrequently, as in the case of transitory insanity, almost the entire article is made up of a quotation. The best authorities are generally quoted, so that a student or general practitioner could learn much from a reading, but to the neurologist there is nothing new in the book.

HOW TO FEEL THE PULSE AND WHAT TO FEEL IN IT. PRACTICAL HINTS FOR BEGINNERS. By WILLIAM EWART, M.B. Cantab., F.R.C.P., Physician to St. George's Hospital, etc. With twelve illustrations. 8vo, pp. xv, 112. New York: William Wood & Co., 1892.

A STUDY of the pulse is at once so interesting and so instructive that the liberally-educated practitioner of medicine cannot afford to be uninformed upon a subject to which really a good deal of importance attaches. As in all else, the information to be gained from a study of the pulse will depend upon the skill of the observer, and skill only comes with experience. The pulse is eminently a practical subject, best taught by actual demonstration. Description, however, may be made useful as a guide, directing ends to be sought, facilitating study, defining technical language, and presenting the accumulated experience of many observers. The little book before us is eminently fitted to fulfil these several indications. Tersely written in clear language, it will prove useful to the student in grasping a subject for the practical application of which the practitioner many times daily finds opportunity. There is one lesson the discriminating reader cannot fail to take away with him, and that is that to be a good clinician he must be a good physiologist. The work concludes with a "Glossary of terms in use at the present time or in the past in connection with the pulse," and a list of the Latin names for the many different kinds of pulse that have been described at one time or another.

ELEMENTS OF MATERIA MEDICA AND THERAPEUTICS. By C. E. ARMAND SEMPLE, B.A., M.B. Cantab., M.R.C.P. London. With 440 illustrations. Pp. xxxii, 480. London: Longmans, Green & Co.; and New York: 15 East 16th Street, 1892.

THIS book will commend itself at once as a practical manual of materia medica and therapeutics. While there exists a multiplicity of truly excellent volumes upon materia medica, the importance of the subject and the constant additions thereto render acceptable any book that will present the matter in a new and agreeable

form. This may be said of the one in question. Its claim for recognition is based upon the peculiarity and simplicity of classification, the comprehensiveness of detail, the multiplicity of illustrations, and the exclusion from its pages of all material not recognized in the 1885 edition of the *British Pharmacopeia* and its Appendix of 1890. Naturally the limitation to those remedies which are officinal forbids the introduction within its pages of many of the more recent drugs which are becoming generally known and employed, but with this exception apparently no efforts have been spared to thoroughly modernize the subject. The American student, however, will find many familiar preparations not mentioned, while their places are taken by preparations as equally unfamiliar. The arrangement adopted is a natural rather than a therapeutic or physiologic one, while the numerous woodcuts lend an additional interest and value to the work.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, held in New York, June 22d, 23d and 24th, 1892.

THE President, DR. C. L. DANA, briefly reviewed the progress of the Association since its inception, and made reference to members deceased since the last meeting, paying special tribute to the memory of the late DR. BIRDSALL.

DR. C. A. HERTER, of New York, read a paper entitled "Researches upon the Etiology of Idiopathic Epilepsy." The investigation was originally undertaken with a view to studying the relation of uric-acid excretion to the epileptic paroxysm. It could not be determined that the seizures of grand mal were determined by an excessive accumulation of uric acid in the blood. Some observations, however, of another kind, had suggested the possibility of a causal relationship, in some cases, between putrefactive processes in the intestines and epileptic seizures. Certain substances in the urine, namely, the ethereal sulphates, had been shown to be derived from putrefaction in the intestine and the extent to which such putrefaction occurred might be inferred from the quantity of these substances in the urine. Thirty-one cases of epilepsy were thus studied. Twenty-nine presented attacks of grand mal. In rare instances only, did the excretion of uric acid before the seizure vary from the limits of health. The urine passed after a seizure, however, generally presented a higher uric-acid ratio than the urine before or about the time of the seizure. In cases of petit mal a continuously high uric-acid excretion had been observed and appeared in some way to be related to the cause of the seizures. Of the twenty-nine cases of grand mal, twenty-one presented unmistakable evidence of excessive intestinal putrefaction. There appeared to be a general correspondence between the seizures and the degree of intestinal putrefaction as gauged by the analysis of the urine.

DR. E. D. FISHER stated that the clinical facts tallied with the deductions arrived at. Given an unstable cortex, there is no reason why the chemical products of intestinal decomposition might not act as the irritating cause of the seizure.

DR. WHARTON SINKLER cited a case illustrative of the action of putrefactive changes in inducing epileptic attacks. The seizures occurred every one or two months, but they were frequently warded off by active purgation.

DR. H. A. TOMLINSON emphasized the fact that keeping the bowels open and seeing to the proper exercise of the epileptic insured fewer convulsions and a less uncomfortable existence.

DR. HERTER expressed the view that the substances that he had been isolating did not act as a cause by themselves, but as irritants upon a predisposition.

DR. J. W. PUTNAM, of Buffalo, read a paper entitled "Sleep Movements of Epilepsy." He related the case of a patient who had a convulsion almost every evening. While waiting to observe an attack, he had several times noticed that the patient restlessly tossed the left arm, while the right was quiet. No movements of the legs were observed; there were no convulsions on the night of the observation, but the mother of the patient stated that during attacks the patient always turned on her left side. The thought suggested itself that a series of observations of epileptics during sleep might show similar movements, which might be of a localizing value.

DR. ISAAC OTT, of Easton, read a paper on "The Seat of Absinthe Epilepsy." He reviewed the various experiments that had been made in localizing convulsive movements, dwelling especially upon the absinthe tests.

It has been found that after injection into the jugular vein of two drops of essence of absinthe, the facial muscles were involved in a single clonic spasm, passing into a state of tremulous tonic spasm. This order of convulsion passed rapidly down the body until the tonic spasm in the limbs was extremely marked. After a short period the tonic spasms gave way to a long series of clonic twitches. Accompanying these convulsive phenomena there was profuse salivation and sometimes escape of urine, while, in cases in which narcosis had not been employed, unconsciousness and coma were early symptoms. The effect upon the cord was also tested by means of the electric method, using both the galvometer and the electrometer. The results showed that the employment of absinthe gave maximal electromotive effects in the sciatic nerve, through the overwhelming discharge of the highest cortical centers. It was also observed that absinthe caused an additional electric excitation of the centers, producing more energy. Absinthe not only produced typical epilepsy in animals, but also in man. That the convulsions were not due to circulatory changes is generally admitted. The theory of spinal origin has been exploded. The evidence indicates that the seat of origin of tonic and clonic movements in epilepsy is in the cortex, and their expression takes place mainly by means of ganglia seated in the pons. The word cortico-pontal might express the origin of convulsive epilepsy due to absinthe.

DR. HENRY R. STEDMAN, of Boston, read a paper entitled "Separate Provision for Epileptics, both Public and Private," entering a plea for the exclusive care of epileptics in special establishments, on the colony plan, throughout the country. That this is practicable, the colonies for epileptics in other countries, particularly in Germany, have demonstrated. The deplorable condition of these unfortunates in almshouses, in which there are large numbers in most of the States, cannot be too

severely condemned. The usual practice of caring for these patients with the insane in lunatic asylums is a great disadvantage to both classes.

DR. BULLARD said that in Massachusetts steps had already been taken to establish suitable special institutions for the care of epileptics. A bill had been prepared by a special committee and presented to the proper authorities.

DR. FREDERICK PETERSON urged the necessity for energetic support of the measures already taken, and added that if his hopes were realized, 120,000 epileptics would have opportunity for instruction and for leading useful lives.

DR. FISHER said he hoped the movement would meet with every success. Treatment does but little good. What is needed is an opportunity for work.

DR. WM. M. LEZYNSKY expressed the view that it would be undesirable to associate cases of chronic epileptic insanity with ordinary epileptics.

DR. TOMLINSON stated that none of the institutions for the insane in which epileptics are kept is suitably equipped to care for them. It was necessary that epileptics should receive special attention. They often evince a tendency to eat voraciously. Constipation is frequent among them, and the auto-infection thus produced increases the frequency of the seizures. If separate treatment, occupation, and proper diet could be provided, epileptics would doubtless lead more comfortable, and, in many cases, really useful lives.

DR. SACHS expressed himself in favor of provision by the State for epileptics, but thought that much must be done by private endeavors. Many of the younger epileptics had no opportunity for proper education. For these there should be private institutions in which distinct educational advantages should be afforded.

The PRESIDENT stated that, after investigation, he does not believe that there should be State provision for epileptics, at least not at present. There is now an enormous number of defective institutions under political influence. If there were added 15,000 epileptics to the 15,000 insane, the condition of the former would, by no means, be benefited. While the institutions for which Dr. Stedman pleaded are undoubtedly needed, efforts should be made to interest private citizens in their support.

On motion of DR. STEDMAN the following resolution was adopted: "That it is the unanimous sense of the American Neurological Association that the proper care of the epileptic class, so long delayed, be urged upon the public, upon State authorities, and especially upon all interested in the care of the sick and defective poor, whereby they may be relieved from asylums and almshouses, and may receive the required care in such separate establishments as their deplorable situations demand."

DR. E. C. SPITZKA, of New York, read a paper on "A New Symptom Indicating Combined Cerebellar and Spinal Incoördination." He reported the case of a child whose attitude and appearance were characteristic of that form of pseudo-hypertrophic paralysis in which the atrophy of the arms markedly antedated wasting in the lower extremities. Whether dressed or undressed, under examination and observation or not, the patient had a habit, with his right hand, the thumb and fingers flexed, of making a sudden motion toward the nose; at the same time there was a straightening in his attitude as if all the muscles involved in maintaining the erect posture were in action. A peculiar expression would cross his face, the head and eyes being turned toward the approaching finger. The child had also imperative conceptions, and a fear of going under a certain tree, a terror, late in the day, of a Newfoundland dog, for which at other times he showed great affection. He had also a terror of the stairs, and even on a level he had an impression as of a yawning precipice. The mother stated that three members of her husband's family were in insane asylums—a brother, a sister, a first cousin, and the grandfather. The uncle and cousin had exhibited exactly the same motion of the hands. The father of the child had some slight ataxia in the hands.

Dr. Spitzka related that he had seen four other patients who presented similar strange automatic movements; in two cases these were bilateral and limited to the arms; in the third they were associated with salaam movements of the head and neck; in the fourth, there was a tendency to a hop-skip-and-jump action. The fourth case was the only one in which there would have been any doubt as to the interpretation of the symptoms had it not been for the bad family history. The patient presented a movement strongly resembling that of the first patient, exceeding it, however, as regarded the turning of the head and neck; the index finger alone was raised and slightly curved, and the patient would start two or three times a minute to imitate the motion that one would make in saying, "I hear a noise there." There was a fixed hallucination of sound, located, the patient said, exactly six inches in an accurately defined direction from the right parietal bos. The patient eventually died of diarrhea, and an autopsy was obtained. No structural disease either of the cord or brain could be found. There was a heterotopia parallel with the claustrum in the region corresponding with the posterior slope of the island of Reil on the left side, and some peculiarities of the gyri that were regarded as abnormal. The convolutions were asymmetrical and atypical.

DR. B. SACHS, of New York, presented "A Further Contribution to the Pathology of Arrested Cerebral Development." He dwelt upon a small group of cases that run in families; the children appear to do well until between the fifth to the eighth month, when a retrograde movement sets in. The cerebral functions, sensory and motor, gradually become impaired. The child soon becomes idiotic, blind, and more or less paretic, death taking place from marasmus. The case reported occurred in a sister of the child whose brain had been reported upon five years before. The child when first seen was thirteen months old. It was born at full term, a perfectly healthy infant, was nursed at the breast, and had appeared to be developing finely until the age of eight months, but from that time on there had been steady retrogression. Close examination showed that the child could not hold up its head; nor could it sit up unless supported; it had no perception of light; the pupillary light-reflex was gone. There was slight sense of hearing, but the child could not distinguish between sounds. There was a spastic condition of the upper and lower extremities. There were no spontaneous movements of any sort, the child sitting listlessly on the

nurse's lap. The knee-jerks on both sides were distinctly exaggerated; no ankle-clonus was obtainable; the plantar reflexes were also increased. The resemblance to the first child was very close in every respect, except that the paresis was more spastic. The condition grew steadily worse, and the child died of marasmus at the age of twenty months. A week before death there had been considerable fever and several convulsive seizures. The autopsy was performed twenty-two hours after death. Most careful examination of all the organs, and of the larger glands failed to detect evidence of syphilis. The skull was symmetrical, of good size, but was unusually thin; the fontanels were closed, but still transparent. The dura was adherent to the skull, so that the brain had to be removed with the calvarium. As in the case of the first child, the brain was firm to the touch, almost as hard as a brain that had been in Müller's fluid for some weeks. The pia could be easily detached, and the cortex, though pale, presented no unusual appearances. The cord presented no abnormal conditions. Very careful microscopic studies of sections of the ganglia, pons, medulla, and cord were made. Marked changes, identical with those present in the first case, were found in all parts of the cortex. In all of the sections examined, not a single normal pyramidal cell could be discovered. The cell-bodies were altered either in shape or in general appearance; the cell-nuclei and the nucleoli were distinct enough, but were surrounded by an altered cell-body, which did not properly take the ordinary strain. The neuroglia cells appeared somewhat increased and the tissue rather dense. The bloodvessels were present in at least the usual proportion, most of them being filled with blood, but there was no sign of any active inflammatory condition. The condition appeared to be a true *agenesis corticalis*.

DR. SACHS and DR. A. G. GERSTER presented a "Report upon the Surgical Treatment of Epilepsy." The cases operated upon were selected with considerable care. They were either of distinctly traumatic origin or such in which a strictly localized convulsion pointed to a limited focus of disease. Cases of general epilepsy of non-traumatic origin were not subjected to operation. In regard to the determination of the brain areas to be operated upon, it was the custom to map out upon the skull with the greatest care in advance of the operation the exact site of the various divisions of the motor areas. In most cases this is quite unnecessary, as the application of the faradic current to the dura would help to localize centers much more accurately than any of the customary rules. While this method will be found entirely satisfactory in cases of ordinary brain-lesion, the morbid brain, as in cases of tumor or in cases in which the brain-tissue had been seriously altered by disease, might not respond as promptly to the current. In such cases the older method of determining the areas would have to be resorted to. The first and most notable result of the operations was that not a single decided cure could be claimed. In several of the cases, there had been marked amelioration immediately after the operation; in some the improvement had lasted a few months, but in every case the attacks recurred after the lapse of several months or less. Operative procedure accomplishes so little because the cases come under notice after the epilepsy has been established for many years. It is now generally conceded that though a focus of disease is the actual cause of the epilepsy, this epilepsy does not as a rule manifest itself until widespread changes have appeared throughout the entire brain. The time that elapsed between the infliction of the initial lesion and the development of these secondary changes corresponds quite accurately with the period of time between the traumatism or the initial disease and the development of the epilepsy. The excision of the cortical tissue after the establishment of epilepsy is of questionable merit. The only hope from surgery is in the prompt interference in all cases of traumatism to the skull, to remove the focus of disease before secondary changes have been set up.

DR. G. J. PRESTON, of Baltimore, read a paper entitled "Some Contributions to the Muscular Sense." The following is a summary of his deductions: The posture-sense is the result of afferent impulses derived from muscles, tendons, articulations and their coverings, and bones. It is independent of and separable from general tactile sensibility, and can possibly be distinguished from the other members of its class, as the pressure-sense, for example. The course of these impulses through the cord is almost certainly by means of the posterior columns. They probably pass into the corpus restiforme and the cerebellum. In all probability they pass through the anterior portion of the posterior third of the posterior limb of the internal capsule, occupying an intermediate position between the motor and sensory fibers in this region. Without positive data on either side, it seems most probable that the center for the posture-sense is located in one of the cell-layers of the motor cortex.

DR. H. H. DONALDSON, of Worcester, read a paper "On the Extent of the Visual Area of the Cortex in Man, as Deduced from a Study of Laura Bridgman's Brain." In Laura Bridgman's case vision had been lost in the left eye at twelve years of age. When first examined the right cortex was found to be thinner than the left. The posterior portions of both hemispheres being compared, it was found that on the right side the cortex was thinner over an area that corresponded pretty nearly with that described as representing the visual area.

DR. DONALDSON also read a paper on "The Criminal Brain; Illustrated by the Brain of a Murderer." Examination of the brain of a murderer of undoubtedly criminal characteristics showed that it did not present the confluent fissures described by Benedict as characteristic of criminal brains. It is maintained that many of Benedict's so-called characteristics are to be found in the normal brain. It has been determined by comparison that there are more confluences in normal brains than in those of criminals. If increased fissuration is a criminal characteristic, other things being equal, this would imply an increase of gray matter; therefore, low-type brains might be said to have proportionately a larger amount of gray matter. Undoubtedly, the criminal brain could be picked out of a mixed lot, but only by virtue of general characteristics; and there could be no certainty that all criminal brains could be thus selected. The characteristics of degeneracy are such as were to be found in the rest of the body, and are not sufficiently marked to be expressed in a systematic manner.

DR. COLLINS related that in holding an autopsy on a murderer who had lost his life in attempting to take that of a New York financier, he had found really remarkable structural changes; whether these were the result of retrograde changes during life or represented an inherent structural absence from the beginning he could not say. The fissure of Rolando was very shallow, the gray matter thinner than normal. The ascending parietal convolution was small and the entire left hemisphere gave an idea of abnormal changes of conformation.

DR. CHARLES K. MILLS expressed the view that there are many misconceptions on the part of those who criticised the observers who had reported aberrations and irregularities in the brains of criminals. No one believes that all criminals present a brain-anatomy that would enable them to be ranged under a special type. Criminals belong to very different classes. A criminal type of brain could be expected from those who were victims of a bad heredity or very early arrest. Paranoiacs, criminals, idiots, imbeciles, those generally who were victims of arrested or abortive development, would probably present brain-abnormalities of a gross kind.

DR. KNAPP stated that it is as vague to speak of a criminal brain as it would be to speak of an insane brain, classing together indiscriminately mania, melancholia, paranoia, and general paralysis.

DR. F. X. DERCUM, of Philadelphia, presented a "Description of a Chinese Brain." The greatest circumference of the skull was twenty-one inches, or 55.3 cm. The naso-occipital arc was 32 cm; the naso-bregmatic arc, 13; the bregma-lambdoidal arc, 12; the lambdo-occipital, 7. The brain, without the dura and without draining, weighed forty-seven ounces. It was anemic, but not edematous. In the right cerebral hemisphere the fissure of Sylvius was very short, and turned sharply up, ending at a point just vertically below the lower extremity of the inferior retrocentral fissure. The fissure of Rolando was normal; it did not quite reach the longitudinal fissure above. The central convolutions were narrow, measuring about 2 cm. in width. The first and second frontal fissures were distinctly outlined, and did not run into other fissures. The inferior and superior precentral fissures were distinct and normal. Anteriorly the interparietal fissure connected superficially with the retrocentral, but was separated by a low, bridging convolution. It did not run into the occipital lobe, but curved up and dipped into the longitudinal fissure. The anterior occipital fissure was plainly marked. The parieto-occipital fissure was deep and wide, and on opening it a small convolution lay at the bottom. There was no inferior *pli de passage*. The first temporal fissure ran into the fissure of Sylvius. In the left hemisphere the fissure of Sylvius was normal. The first temporal fissure ran into it, as did the fissure of Rolando. The fissure of Rolando was marked, and ran into the fissure of Sylvius. The first and second frontal, and the precentral fissures were normal. The interparietal fissure was marked, and ran into the occipital lobe. The parieto-occipital fissure resembled that of the right hemisphere. The anterior occipital fissure was marked. There was no inferior *pli de passage*. The first temporal fissure ran into the fissure of Sylvius, and was broken in two places.

In all of the brains of Chinese so far examined an unusual tendency to transverse or perpendicular fissuration has been present. There was also unusual sinuosity of the fissures. Of the gross peculiarities, there was a marked obliquity or eversion of the basal surface of the frontal lobe. In both of two specimens previously described complexity was given to the frontal lobes by the appearance of well-marked medi-frontal elements. In the present specimen an added frontal fissure was present in the left lobe, but was comparatively short. In the right lobe only traces of it were found. In all of the specimens the cuneus and the occipital lobe were rather small. Owing, probably, to the unusual sinuosity of some of the fissures, together with the excessive transverse fissuration, these brains have a physiognomy, as it were, of their own. In general appearance they were certainly different from the average white brain, and very different from the brain of the negro.

DR. JAMES HENDRIE LLOYD, of Philadelphia. read a paper on "The Association of Hysterical Trembling and Anorexia Nervosa, with Report of a Case." The case was that of a young woman who had been first observed at a remote farm-house in Pennsylvania. She had been ill for two years. She presented a peculiar rhythmic, constant tremor, which was not paralysis agitans. The tremor occurred in waves of exacerbation and opisthotonic spasms every minute or so. The patient had hysterogenic zones, pressure over which would induce a spasm. She also presented the condition described by Gull as anorexia nervosa. By a mistake, a large dose of ordinary saltpeter had been given, instead of sulphate of magnesium. While no harm had directly resulted from this error, the mental disturbance had been so great that regurgitation of food had set in and had become the most pronounced complication in the case. The patient was found lying upon her side, with cloths under her chin to catch the regurgitated material. She was emaciated to the last degree. There was no atrophy, but simply inanition. This condition was followed by true hysterical retention of urine, lasting sometimes for two days. Upon removal to a private hospital, the tremor had greatly subsided and regurgitation of food had entirely ceased.

DR. RIGGS cited the case of a woman under his care believed to be suffering from hysterical tremor. The attack came on only during the morning hours. No stigmata could be found. There was persistent nausea and continuous headache. Under the usual therapeutic measures the patient had steadily improved.

DR. WEBBER stated that these patients do not really swallow—at least, the food does not pass into the stomach. If food were made to pass into the stomach through a tube the vomiting ceased. The symptoms ceased, and the ability to take food returned, if the patients were removed from home for a time.

DR. PRESTON stated that it is necessary to distinguish between hysterical tremor and the *tremblement nerveuse* of Charcot. There is an hysterical tremor due to distinct cortical inhibition, an absence of stimuli sufficiently close together to insure summation, and hence there is a series of movements resulting in tremor. In a case of hysterical anorexia, with nervous tremblings at intervals, the patient had lost 50 per cent. of body-weight.

DR. MILLS stated that he had seen Dr. Lloyd's case

and considered the diagnosis correct. It is important to determine that the tremor or abnormal movements are not purely hysterical or associated with melancholia or some organic disturbance. A diagnosis of the hysterical character of the tremor is to be made chiefly from the association of other hysterical manifestations. As to the prognosis, many of such cases would outlast their medical observers.

DR. SACHS related the case of a young woman who absolutely refused to take food on the plea that she could not swallow. Efforts were made to administer food by force. She would keep large quantities in her gullet and then go into a corner of the room and eject it. When fed, she would gag and regurgitate a little, but it was not believed that she emptied the contents of the stomach entirely, and it was agreed that it was not true vomiting. Male hysterical patients are much more difficult to handle than female patients. The majority of these patients must swallow. The best proof that they are not without food lay in the fact that they increase in weight. The hystero-epileptic regimen has been followed in these cases by brilliant results. Few cases of hysterical anorexia will resist cold water applied under considerable pressure.

DR. C. K. MILLS read a paper entitled "Folie à Deux, with Remarks on Similar Types of Insanity." He reported the cases of two sisters, the eldest thirty-two years of age, the other less than two years younger. The father was a hard-drinking, quarrelsome man. The first patient had been deranged for three or four years. She had complained of feelings as of something growing in her abdomen, of sickness of the stomach, bloody passages, chills, and other unpleasant sensations. For a long time she had been annoyed by strange voices. She was tormented by others, both at her work and at home, and was made to say very ridiculous things. She apparently had hallucinations of several senses. A stench of blood came up through her throat; at times she was grasped by a hand or hands. Men would appear before her; sometimes they would get on their knees and solicit her. She was full of sexual delusions with reference to men and their designs upon her. The heads of men would appear before her at her work. When she did not see them, she would sometimes feel them or hear them; often she heard their voices talking with her after midnight, saying all sorts of filthy things.

In the second patient the mental disturbance had apparently come on a few weeks after that of the first. The delusions of the first had to some extent, been imposed or communicated to the second. Besides having various physical symptoms, the second patient, who seemed to be weaker both mentally and physically than the other, told the most filthy stories. She said that she knew the men that were abusing her. These patients had evidently become a nuisance both at their home and in the neighborhood. Some of the men they had accused had been threatened by them. They appeared to believe firmly in what they said, and yet at times to appreciate that something was mentally wrong. They eventually went quietly and without resistance to a hospital for the insane, thinking apparently that they might be able to get their troubles straightened after they got there. They presented, as is not unusual, a blending of the characteristics of the three forms of folie à deux—that is, of the imposed insanity, the simultaneous insanity, and the communicated insanity. The influence of heredity was decided; the delusions were persecutory.

DR. MILLS reported "A Case of Rapidly Fatal Motor and Sensory Paralysis, with Autopsy, showing Acute Myelitis Mainly of the Dorsal Cord." The patient, a man thirty-seven years old, with an uncertain specific history, six months before coming under observation had had a large carbuncle between the shoulders. For months he had shown some tendency to drag his feet. For two weeks he had had pain and soreness almost in the line of the right nipple, which extended later into the armpits and down the inner side of the arm. Four days before he was first seen, he complained of severe pain in the loins. On the next day, he was barely able to walk, and in thirty-six hours he could not stand. Twenty-four hours later he was completely paralyzed in both lower extremities, and showed also total loss of sensation as high as the nipples. He had incontinence of urine and feces; the knee-jerks, the muscle-jerks, and the cutaneous reflexes were abolished. This extreme paralysis was fully developed three days after the first symptom of motor impairment became marked. The temperature rose rapidly to 104° or 105°, with a corresponding increase in the frequency of pulse and respiration. Ten days after the onset, the man died. From the fourth to the eighth day his condition did not change much, except that the line of insensibility advanced a little higher and ecchymotic areas appeared on the thighs. The motor paralysis, reflexes, etc., made no improvement. On the ninth day he complained of severe paroxysmal pain in the upper arms. Mucus collected in the larynx, the voice became weak, the surface of the body cold, with some delirium and at times a marked disposition to somnolence. From the ninth day the man kept both forearms flexed and rested them on his abdomen and chest, the little and ring fingers being also flexed. At the autopsy, the vessels of the spinal pia were greatly distended with blood. On section, the periphery of the cervical cord was of good consistence, but the center was much softened. As the sections were made lower down, the transverse area of the softening increased, until in the dorsal region only a shell of solid tissue surrounded a creamy mass. The softening grew less again in the lumbar region. Below the right groin was a swelling containing broken-down glands and pus. The other organs and parts were found to be normal. Microscopic examination showed the nervous tissue in the dorsal region to be almost entirely destroyed. The bloodvessels were distended and there were many scattered hemorrhages. Hemorrhages were also present in the pia and in some of the peripheral nerve-roots. The upper part of the cervical region was but little affected, the lumbar much less than the dorsal. The case was unquestionably one of acute, rapidly spreading myelitis.

DR. SACHS stated that he had seen several cases in which acute myelitis led primarily to death. In the case reported, the analogy with acute tuberculous myelitis suggested itself. Dr. Sachs had seen three cases with such characteristics, in all of which tubercle-bacilli were discovered in the broken-down cord. In cases in which there has been some chronic disease of the spinal cord before exposure to tuberculous infection, the cord is very prone to break down.

DR. PRESTON agreed with the opinion that the case could be considered as one of hemorrhagic myelitis, producing distinct arterial sclerosis. He had seen a case of the kind apparently due to a very limited local tuberculosis of a vertebra. The vertebra was not broken down, and the bone not decidedly involved. There were tuberculous nodules in the coverings of the cord at the point where the myelitis began.

DR. MILLS and DR. JOHN B. DEAVER reported "A Case in which Exploratory Trephining and Ligation of the Vertebral Artery were Performed, Autopsy showing Gliomatosis of the Cerebellum, Pons, and Oblongata, with Hydrocephalus and Hydrorrhachis; Opening in the Skull from Continued Pressure." The patient was a boy, eleven years of age, who, in December, 1889, had commenced to complain of pain in the head and some stiffness of the neck. To this were slowly added failure of sight, attacks of nausea, occasional paroxysms of violence or excitement, strabismus, staggering in walking—a little more to the left than to the right—a feeling of dizziness described as "going over," and shortness of breath. Before the operation, double optic neuritis in an advanced stage was present. Hearing and taste were not impaired. There was no motor paralysis, no disturbance of common sensibility, and no nystagmus. On examination, a pulsating tumor was found in the occipital region, slightly protruding through a small opening in the skull to the left of the occipital protuberance. A distinct thrill and bruit seemed to be present. Three scars were noted on the posterior aspect of the head, one just above and to the right of the opening.

A tremor was felt resembling that made by an arteriovenous aneurism. Pressure upon the carotid arteries lessened the pulsation and bruit. The opening in the skull was enlarged, so as to examine the supposed aneurism, which appeared to be in the line of the lateral sinus, but when this was done the character of the swelling was too uncertain to go further. An exploring needle was introduced; on its withdrawal there was considerable bleeding, only arrested by long-continued pressure. Subsequently the left vertebral artery was ligated, but without beneficial results. After the operation, the pupil on the side corresponding to the cicatrix was contracted. The patient slowly grew weaker, and died several months after the operation. At the autopsy a gelatinous mass was found occupying much of the fourth ventricle, reaching from or into the middle lobe of the cerebellum and both cerebellar hemispheres. The ventricles of the brain and their horns were enormously dilated, and at several places at the base rupture had almost taken place into the cranial cavity. When the spinal cord was severed from the medulla oblongata, the central spinal canal was found to be one-sixth of an inch in diameter, and from it much fluid escaped. The chief points of interest were with reference to the diagnosis from aneurism, the mechanism of the process by which the opening in the skull resulted, and the production of the hydrocephalus and hydrorrhachis.

DR. L. C. GRAY, of New York, reported "A Case of Huntington's Chorea; also one of Congenital Huntington's Chorea, the First on Record." The first case was in a man in whose family the disease had manifested itself for many generations. The movements and progressive muscular tremors had appeared when the patient had reached the age of forty-five years. The swaying and dancing movements were not considered those of chorea. The second case was in a child, and was thought to be one of congenital Huntington's chorea. There had been no similar trouble in other members of the family and the general history was negative. The choreic movements had been noticed immediately after birth.

DR. J. H. LLOYD expressed the view that so-called Huntington's chorea, though clinically similar to ordinary chorea, is dependent upon a different pathology. Mental failure is usually associated with adult chorea.

DR. SINKLER stated that the case presented differed from ordinary chorea, and had probably begun as spinal disease. It was much like so-called spinal chorea.

DR. COLLINS reported having observed the case of a child of eleven in whom the movements, which dated from birth, were more characteristic than in the case presented, in whom the lesion was probably one of the medullary areas, the choreic movements being associated with the lack of development in these areas.

The PRESIDENT presented a case of hereditary chorea in a Scotchman in whose family the disease had appeared for four or five generations.

DR. PHILIP COOMBS KNAPP, of Boston, read a paper on "Traumatic Nervous Affections." He presented a summary of ninety cases. Pain in the back was present in fifty-six. Five cases were due to direct injury to the cord, resulting in paraplegia. In four cases, there were symptoms of insidious onset referable to the cord: paresis, vesical disturbances, and a slight spastic condition; the lesions were thought to be chiefly in the lateral columns. Systemic diseases, such as tabes or spinal muscular atrophy, were rare. Thirteen cases were regarded as of more distinctly cerebral origin. In some cases the symptoms indicated a focal lesion, hemorrhage, fracture, or meningitis. Twelve cases were believed to have an organic basis, a diffuse sclerosis of the cerebral nervous system. Four of these had terminated fatally. Four others were thought to belong to this class, but they were classified as doubtful. Twenty-six cases were classed as neurasthenia. Seventeen cases were classified as hysteria. Most of these also presented symptoms of neurasthenia. Pure hysteria was rare. Successful simulation was believed to be extremely rare. The prognosis depends upon the form of disease.

DR. E. C. SPITZKA, of New York, made some remarks on "The Treatment of Syphilitic Nervous Affections." He stated that empirically, the more rapidly a syphilitic lesion of the central nervous system is developed, the more rapidly fatal or radically curable it is. An established sclerosis of non-syphilitic origin will be as readily affected by the iodides or mercury as one of syphilitic origin. The later the outbreak of nervous sequelæ, in a case of paretic dementia of syphilitic origin, the less useful the iodides and the more useful are mercurial preparations and the associated baths. An interrupted plan of treatment covering a long period of time is more applicable to late cases than the energetic single course.

DR. THEODORE H. KELLOGG, of Flushing, read a paper on "The Toxic Origin of Insanity." He stated that it is established that a considerable percentage of all mental disorders have a toxic etiology. Whenever a

poison entered the human system, and through its presence directly or indirectly caused prolonged derangement of the mental functions, the insanity may be considered toxic. The exciting cause will be most active in cases having a native instability of nervous centers. The toxic agent may be vegetable, animal, or mineral. It may be generated as an organic virus in the bodies of others, or it may originate through metabolic tissue-changes in the patient himself, as in the auto-intoxications. It may gain access to the system through the alimentary canal, by the respiratory tract, or through the cutaneous surface, and may act on the cerebro-spinal centers or the sympathetic nervous system by direct affinity, or through pathologic changes induced in the blood, or in the internal organs.

DR. TOMLINSON contended that a toxic influence could not produce insanity of itself, in the absence of a preëxisting instability of the nervous organization, inherited or acquired. Insanity resulting from the misuse of narcotics and alcohol is to be considered as a manifestation of defective nervous organization, exaggerated by the toxic influence these substances exert upon the organism. In auto-infection the same conditions must necessarily exist, else auto-infection would be a more common cause of insanity.

DR. H. A. TOMLINSON, of St. Peter, presented "A Study of the Sensory and Sensory-motor Disturbances Associated with Insanity, from a Biological and Physiological Standpoint." For convenience of study, he arranged the sensory and motor disturbances associated with insanity as follows: Sensory—Disturbance of general sensation, including anesthesia, analgesia, paresthesia, and disturbed muscular sense; disturbance of special senses, including auditory, visual, olfactory, gustatory, and tactual hallucination; illusions, manifested by associated perversions, and lastly visceral hallucinations. Motor disturbance—Tremor, local or general; automatic associated movements; paresis and paralysis, involving special muscular groups or general muscular function; vasomotor disturbance, spasm, and convulsion. He summarized the result of his studies as follows: The application of the theory of evolution to the study of the development of the nervous system, and the normal manifestation of its activities, furnishes the best and most satisfactory basis for the study of the hereditary and acquired imperfections in its structure, with the resulting abnormal manifestation of functional activity, both sensory and motor, as well as the influence of the environment of the individual in determining the nature of the perversion. He expressed the opinion that the future progress in the study of insanity and its associated disturbances, especially its prevention and cure, would depend upon a study of biology and physiology, rather than pathology.

DR. THOMAS J. MAYS, of Philadelphia, read a paper entitled "Pulmonary Phthisis in its Relation to Insanity and to Other Neuroses." [See THE MEDICAL NEWS, July 16, 1892, p. 57.]

DR. J. J. PUTNAM, of Boston, reported "A Case of Akinesia Algera." The patient was a middle-aged man, who belonged to a family of nervous invalids. His trouble had existed since childhood and had gradually increased in intensity. The most conspicuous symptom was excessive pain immediately following the use of the muscles. There was no sign of any trophic changes. The man was well formed, had a delicate skin, and presented no other symptom. There was no tenderness.

DR. J. J. PUTNAM also read a paper entitled "Cephalic Tetanus." He reported a case in which the patient, after having five teeth filled, had been seized with stiffness of one side of the face and neck, followed by spasms so severe that the teeth were ground together; the spasm was continuous. The temperature was 101° F. After some six or eight weeks the symptoms passed away, but as they abated the opposite side became involved, although in a less degree.

NEWS ITEMS.

Professor v. Helmholtz, of Berlin, has been elected a member of the French Academy of Sciences.

Professor His, of Leipsic, has been elected a foreign member of the Stockholm Academy of Sciences.

Biermer, the distinguished German clinician, died recently at Breslau, sixty-five years old. It was he that announced pernicious anemia as a distinct disease.

Henry A. Riley, A. B., Ll.B., a frequent contributor to medico-legal literature, died of heart-disease in New York on June 9.

Dr. Julian J. Chisolm, LL.D.—At the recent Commencement of South Carolina College, at Columbia, S. C., the honorary degree of Doctor of Laws was conferred upon Dr. Julian J. Chisolm, of Baltimore.

Professor Du Bois-Reymond, of Berlin, has been elected a member of the Hetaireia Epistemonidiæ of Athens, of the Royal Scientific Society of Edinburgh, of the National Academy of Sciences of the United States, and of the Royal Belgian Academy.

The Cartwright Prize of the Alumni Association of the College of Physicians and Surgeons of New York, amounting to $500, will be awarded in June, 1893, for the best essay upon any subject connected with the Science of Medicine. An essay must contain the results of original investigation, and must be the work of a single author. Essays in competition must be sent to the Secretary, Dr. T. M. Cheeseman, 46 East 29th Street, New York, on or before April 1, 1893.

Dr. G. T. Lewis.—At a meeting of the Staff of Wills Hospital, held July 14, 1892, the following preamble and resolutions were adopted:

Whereas it has pleased God to take from the sphere of his earthly calling our brother and colleague, George Thomas Lewis, an Assistant Surgeon of this Hospital, it is

Resolved, That we place upon record our appreciation of his devotion to his duties in this house, of his high sense of honor, and of a culture beyond common.

Resolved, That we offer our deepest sympathy to the family of our late colleague, and that a copy of these resolutions be published in the medical and daily journals.

THE PATHOLOGY OF INTESTINAL OBSTRUCTIONS FOLLOWING ABDOMINAL AND PELVIC OPERATIONS.

BY WILLIAM EASTERLY ASHTON, M.D.,

PROFESSOR OF GYNECOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

NOTWITHSTANDING the brilliant results that have been attained in modern abdominal and pelvic surgery, there is still much to learn and much to improve upon in our operative technique, before some of the distressing after-results of these operations are prevented, or at least rendered less frequent. Among the most important of these post-operative complications I would include intestinal obstructions. An enormous amount of literature has been written upon acute intestinal obstructions as a surgical affection, and the subject is, very properly, receiving, in our medical societies, the attention it deserves; but as yet little has been done toward solving the problems suggested by bowel-obstruction following abdominal and pelvic operations. It is, therefore, my purpose in this paper to enter into the pathology of these obstructions, and to discuss such views of the subject as my own experience and that of other surgeons my suggest.

In discussing the pathology of bowel-obstructions following intra-peritoneal operations I shall limit myself strictly to those causes dependent upon operative interference and not refer to the causes of acute obstruction from the standpoint of a surgical affection.

I shall classify the causes of post-operative obstructions as follows:

1. Adhesions between the intestine and raw surfaces.
   - *a*. To an omental stump.
   - *b*. To denudations of the pelvic and parietal peritoneum.
   - *c*. To the edges of the vaginal wound following supra-pubic or vaginal hysterectomy.
   - *d*. To a pedicle.
   - *e*. To raw surfaces on the intestinal wall.
2. Paralysis of the intestines.
3. Local spasm of the intestines.
4. Impacted feces.
5. Bands of inflammatory lymph.
6. Adhesions between coils of intestines or between the gut and neighboring parts, due to traumatic inflammation.
7. Kinking or twisting of the intestine due to faulty technique.
8. Including the intestine within the loop of a suture of the abdominal wall or between the edges of the abdominal incision.
9. Slipping of a coil of intestine through a slit or an aperture.

Adhesions Between the Intestines and Raw Surfaces.—By far the greater number of bowel obstructions are due to this cause. A knuckle of gut becomes attached by adhesive inflammation to a denuded surface, a kink results and obstruction of the bowel follows.

Naturally the question will be asked: How do we explain the fact that so few cases of obstruction occur from this cause when there are so many bad pelvic cases requiring the separation of extensive adhesions? My answer is that kinking does not necessarily follow the fixation of a knuckle of intestine, unless the gut adheres in an abnormal position. In other words, if the normal position of a coil of intestine is near the position of the denuded surface, to which it adheres, obstruction will not, as a rule, follow. Furthermore, I believe that many of the cases that die after abdominal and pelvic operations, in which death is ascribed to peritonitis, are in reality undiagnosticated bowel-obstructions.

The following cases present points of great interest in connection with this class of obstructions:

CASE I, reported by Meredith.[1] Section for a double cystoma, with extensive adhesions. *Secondary section* on the eighth day. The peritoneum was intensely red and congested, evidently in the first stage of acute inflammation. "Attention was attracted to a coil of greatly distended small intestine which was badly kinked and obstructed in consequence of the traction exerted upon it by a portion of the ligated omentum, which was closely adherent to its surface." There was no other obstruction. The patient recovered

CASE II, reported by Krug.[2] Section for double pyosalpinx and ovarian abscesses. Adhesions especially extensive behind uterus. Irrigation and drainage. *Secondary section* on the fourth day. Signs of beginning peritonitis. A portion of the descending colon was found glued fast as an angular loop to the posterior surface of uterus. The patient recovered.

[1] London Lancet, 1886, p. 64.

[2] Am. Journ. of Obstet., 1890, xxiii, 1371.

CASE III, reported by Ahern.[1] Section for a large cyst of the right ovary. Adhesions to the brim of pelvis on the left side and to the sigmoid flexure. The raw surfaces, two in number, each half an inch in diameter. No drainage. *Secondary section* on the ninth day. The upper part of the small intestine congested and distended, adherent to the pedicle and to both denuded surfaces. Below the adhesion the bowel was contracted. The coil of intestine at the point of adhesion formed an acute angle. The patient recovered.

CASE IV, reported by Anderson.[2] Section for an ovarian cystoma, adherent to the parietal peritoneum, just above the position of the cecum. *Secondary section* on the twentieth day. A coil of small intestine adherent to the raw surface just above the position of the cecum. Below the adhesion the gut was collapsed, above distended. The patient recovered.

CASE V, reported by Coe.[3] Vaginal hysterectomy. Uterus retroflexed and adherent. An ovarian cyst on the right side, punctured and removed. No ligatures were used. Two forceps were applied to each broad ligament, and two pairs to bleeding-points in the utero-sacral folds. The peritoneal wound was left open. A tampon of iodoform-gauze was applied. At the *section* on the fifth day a loop of small intestine was found adherent to the right edge of the vaginal wound. There was no peritonitis. The gut was distended above the adhesion and contracted below. The patient died on the following morning from shock.

The following cases of "Ileus after vaginal extirpation of the uterus," quoted by Coe, from a paper by Reichel,[4] are of great interest:

CASE I.—*Section* on the seventh day. The lower part of the ileum was attached to the edge of the vaginal wound. The gut above was distended. There was no peritonitis. The patient died on the table.

CASE II.—(Olshausen.)—*Section* on the ninth day. A coil of ileum was found adherent to the edge of the vaginal wound. The gut was bent at an angle. The woman died in twenty-four hours. *Post-mortem*—Diffused peritonitis was found. Two other coils were found attached to the edge of the vaginal wound.

CASE III.—The patient collapsed and died on the eighth day. *Post-mortem*—Coils of intestine were found adherent to the edge of the vaginal wound. The gut above was greatly distended. The large intestine contained fecal matter. The obstruction was, therefore, not complete. There was no general peritonitis.

The following four cases of obstruction consequent upon vaginal hysterectomy are also quoted by Coe:

CASE I.—Blakemann's[5] patient died on the seventh day. *Post-mortem*—The lowest part of the ileum was found adherent to the edge of the vaginal wound. The gut was distended and bent at an angle.

CASE II.—In Leopold's[1] patient death took place on the fourth day. *Post-mortem*—Two coils of intestine were found adherent to the edge of the vaginal wound. The gut was bent at an angle.

CASE III.—Landau.[2] *Section* on the seventh day. The gut was adherent to the edge of the vaginal wound. The patient died on the following day.

CASE IV.—Coe's[3] patient. *Section* on the second day. Two or three coils of ileum were found adherent to the edge of the vaginal wound. Gas escaped per anum after the intestine was detached. There was no peritonitis. Death took place in fourteen hours.

These cases illustrate in a forcible manner the explanations and dangers of obstructions due to raw surfaces. In every one of the abdominal sections the obstruction occurred at a point where adhesions had been separated at the time of operation. Again, in every instance the intestines were fixed in an abnormal position, and at the point of fixation formed a more or less acute angle. In the case reported by Krug, in which he found the descending colon "adherent as an angular loop to the posterior surface of the uterus," we have an instructive illustration of these points. The cases of obstruction following vaginal hysterectomy quoted also demonstrate clearly the cause of bowel-fixation and kinking dependent upon adhesive attachment of the intestine to a raw surface.

The practical operative lesson that all of these cases teach is that in performing secondary section for their relief we should know where to look for the seat of obstruction if we have kept in mind the position of surfaces denuded at the time of the original operation.

Paralysis and local spasm of the intestines; impacted feces.—As the pathology of all these causes of obstruction is the same, I shall discuss them under one heading. First, however, I shall cite some cases illustrating this class of intestinal blocking:

CASE I.—This case occurred in my own practice. The section was made for double pyosalpinx, with slight adhesion. Irrigation was employed, but no drainage. Death took place on the fifth day. *Post-mortem*—The small intestine for a distance of eight inches from the ileo-cecal valve was tightly contracted, causing absolute obstruction. Above the contraction the gut was greatly distended. At the seat of constriction the bowel was red and congested, but no lymph was found. The abdominal cavity was dry. There were no adhesions.

[2] Berliner klin. Wochenschrift, 1888, No. 10.
[3] Am. Journ. of Obstet., 1890, xxiii, 469.

CASE II.—Reported by Baldy.[1] Supra-pubic hysterectomy. Extra-peritoneal treatment of the stump. *Secondary section* on the sixth day. Intestinal evacuation and drainage. Death in twenty-four hours. *Post-mortem*—The intestines were found free, "but in one or two places they had contracted so as to feel like hard cords."

CASE III.—Reported by Baldy.[2] The section was made for double pyosalpinx. Inflammation of some of the pelvic loops of intestine was found. *Secondary section* on the fourth day. The bowels were enormously distended. Intestinal evacuation and drainage. Death took place in twelve hours. *Post-mortem*—"There was nothing abnormal found excepting the peritonitis affecting the coils of intestine in the pelvis. There was a slight adhesion of these coils to one another."

CASE IV.—Occurring in my own practice. The section was made for chronic inflammation of the appendages. Dense pelvic adhesions were found. A *secondary section* was made on the twentieth day. The small intestines were somewhat distended, but there was no evidence of peritonitis or of pus. The descending colon was tightly packed with hard feces from the splenic to the sigmoid flexure. Bands of lymph constricted slightly the bowel near the sigmoid. The patient recovered.

The correct explanation of obstructions due to local spasm or paresis of the bowel will, most probably, be found in a study of the influence of various stimuli upon the nerves controlling intestinal peristalsis. The intestinal walls contain an automatic motor-apparatus—the plexus of Auerbach—which influences the peristaltic action of the bowel. "If this center is not affected by any stimulus, the movements of the intestines cease—comparable to the condition of the medulla oblongata in apnea. The same is true just as in the case of respiration during intra-uterine life, in consequence of the fetal blood being well supplied with O. This condition may be termed aperistalsis. It also occurs during sleep, perhaps on account of the greater amount of O in the blood during that state. All stimuli applied to the plexus myentericus increase the peristalsis, which may become so very violent as to cause evacuation of the contents of the large gut, and may even produce spasmodic contraction of the musculature of the intestine. This condition may be termed dysperistalsis—corresponding to dyspnea. The condition of the blood flowing through the intestinal vessels has a most important effect on peristaltic movements. The continued application of strong stimuli causes dysperistalsis to give place to rest, owing to over-stimulation, which may be called intestinal paresis or exhaustion."[3]

With these facts before us concerning the effects of the absence or the presence of stimulation upon intestinal peristalsis we are better able to explain the pathology of these obstructions. In the first twenty-four or forty-eight hours after an abdominal section, if the case be doing well, the intestines are in a condition of aperistalsis. There are several factors concerned in bringing about this state. In the first place, the preparatory treatment of the bowels with salines, the liquid diet, and the absence of food after section leave the intestines comparatively empty, thus removing the intestinal contents as a factor in stimulating peristalsis. Again, the rest in bed for two or three days before an operation, and the enforced quiet afterward add largely to the absence of intestinal activity. This condition is not only observed after an abdominal section but also after parturition, and in fact in all cases in which the patient is required to lie quietly in bed for some time. The well-known fact that changing the position of a patient in bed relieves the tympany in some cases and favors the downward movement of gas shows the effect of exercise upon intestinal peristalsis.

The causes of operative stimulation of the intestines are exposure to the air, lowering of the temperature, bruising, operative procedures, irritating fluids, septic materials, and a neglect to thoroughly empty the bowels prior to operation. We have found that dysperistalsis and paresis depend upon the same cause, namely, an irritation of the motor center of the intestine, but the intensity and duration of the abnormal stimulation alone determine the difference between the two conditions. For example, simple intestinal congestion would most probably, even if long continued, result in a condition of dysperistalsis, while a severe inflammation on the other hand would cause a state of paresis.

In Cases I and II there was present a condition of intestinal dysperistalsis causing the obstruction. In both cases, at the beginning, this condition alone existed, but subsequently paresis of the gut above the constriction occurred, from the continued effort of the intestine to push its contents beyond the obstruction. The increased amount of gas and fluid in the bowel also aided in producing exhaustion, as these necessarily constituted a source of continued irritation. In Case I the intestinal spasm was probably the result of the congestion that was practically limited to the seat of constriction of the bowel. The cause of this congestion is difficult to determine. Possibly, it may have been due to the irritation of the intestine produced by the pus that escaped when the tubes were delivered, or the bowel may have been bruised during the operation and a traumatic peritonitis was developing at the time of death. In Case II the notes of the post-mortem examination were too superficial to be of

[1] Journal of Gynecology, August, 1891. [2] Ibid.
[3] Landois, 2d Amer. edit., p. 263.

any value in determining the cause of the nodulated condition of the intestines. Case III was clearly one of intestinal paresis due to peritonitis. The adhesions found between coils of intestine after death were evidence that the peritonitis that had existed at the time of the operation had continued.

Case IV is of especial interest. The patient had a bowel-movement in forty-eight hours and everything was doing well until she fell out of bed in her sleep on the third day after operation. Now, what had happened to bring about obstruction from fecal impaction after this accident? I believe that the fall caused a traumatic peritonitis, which resulted in paresis of the colon, and while the bowel was in this condition fecal accumulation took place. After the intestine had regained its normal activity it was then unable to empty itself, on account of the great amount of fecal matter that had collected. In addition to this want of power in the gut there was also more or less constriction from bands of lymph at the sigmoid flexure, which rendered the downward passage of the feces difficult.

Bands of inflammatory lymph. As the result of intra-peritoneal inflammation following abdominal and pelvic operations, lymph is poured out upon the intestines, and coils of the gut become more or less adherent to each other. As a rule, no bad results ensue, but if the adhesions destroy the normal relations between the coils, or if a knuckle of gut is constricted by a band of lymph, then kinking or strangulation follows. These obstructions do not manifest themselves early after operation, because, usually, no serious interference with the movement of the intestinal fluids occurs until the bands of lymph begin to organize and contract. Montgomery[1] reports an interesting case of volvulus caused by bands of inflammatory lymph. Five weeks after the original operation for peritonitis, symptoms of obstruction appeared, associated with fecal vomiting. "The intestines were found matted together, so that over a yard of small intestines had to be forcibly liberated from extensive adhesions. The muscular coat was torn through at a number of points; a distinct twist was found in the small intestine, which was readily overcome by separating the bands of adhesions." The patient made a good recovery.

Adhesions between coils of intestine or between the gut and neighboring parts, due to traumatic inflammation. These adhesions have always been a subject of great interest to me. They result from an irritation of the serous membrane, caused by the exposure of the intestine to the air, to lowering of their temperature, to handling or to necessary manipulations or operative procedures. Adhesions of this class are, in my experience, a necessary sequence of all intra-peritoneal operations. In fact, they are, I might say, the opprobrium of abdominal surgery, for it must, indeed, be rare to have an abdominal operation not followed by more or less fixation of the viscera.

In my experimental work upon the lower animals this fact has time and again forced itself upon me. For example, I have established a lateral anastomosis in a perfectly healthy dog without resection. At the time of operation not more than ten inches of the bowel were exposed through an incision in the abdominal wall, less than two inches in length, and every precaution was taken in the operative technique. Yet, notwithstanding these facts, when the animal was killed at the expiration of three weeks, after making an uninterrupted recovery, the intestines were so matted together that I was with the greatest difficulty able to separate the seat of anastomosis from the adherent coils of gut. This has been my experience without exception in all work upon the lower animals.

I have seen numerous illustrations of these traumatic adhesions in the human subject during secondary sections or upon post-mortem examination. In the case of a woman at the Philadelphia Hospital, who had died three weeks after a supravaginal hysterectomy, from disease of the kidneys, the intestines were found to be extensively matted together. The hysterectomy was a simple operation, uncomplicated by adhesions; the abdominal incision was small and there was no exposure of the intestines; yet, after death, extensive fixation of the gut was found.

It is a common experience, in performing secondary sections, to find the gut or the omentum adherent to the parietal peritoneum at the site of the original abdominal incision. This fact is so well recognized that great care is always taken in reopening the abdomen to cut to one or the other side of the cicatrix, in order to avoid the danger of wounding a knuckle of adherent gut. Fortunately, traumatic adhesions are, as a rule, not followed by fatal results, as they do not cause kinking or twisting of the gut. They do, however, not infrequently cause remote trouble, by giving rise to colicky pains and a greater or less tendency to constipation.

Kinking or twisting of the intestine, due to faulty operative technique. These obstructions are not the result of adhesions, but occur after anastomotic operations upon the alimentary canal or after the repair of bowel-lesions. For example, a coil of intestine may be kinked or twisted by placing it in

[1] Philadelphia Hospital Reports, 1891.

an abnormal position in establishing an anastomosis; or, again, the bowel may be torn transversely while separating adhesions in the course of an operation, and if the opening be large, suturing the tear may result in fatal obstruction from kinking. Tears in the wall of the bowel, longitudinal to its long axis, even if extensive, may be safely closed with sutures, but a large transverse opening into the gut will, if sutured, almost certainly cause a kink.

Including the intestine within the loop of a suture of the abdominal wall or between the edges of the abdominal incision. At first sight these causes of bowel-obstruction may appear to the surgeon as being extremely unlikely or at least very rare. Yet, if we call to mind our own operations, as well as those of other surgeons, I think all of us will be struck by the fact that such an accident is liable to occur when the abdominal incision is closed. There is but little danger, I admit, of including a loop of intestine when the sutures of the abdominal wall are introduced, as the abdominal contents are protected by a gauze pad or a flat sponge, but it is when they are tied that the accident is likely to occur. After the pad or the sponge has been removed the intestines come in direct contact with the loops of the sutures and press up, more or less, between the edges of the abdominal wound. Naturally, therefore, it is almost impossible for the surgeon to know positively that a portion of the gut has not been caught where the sutures are tied. Of course, if the gut has been fastened to the abdominal incision, no immediate results will necessarily follow, unless the lumen of the intestine has been obliterated, leakage occurs, or kinking takes place. Consequently, in the majority of instances we are not aware that such an accident has occurred. Or, again, if the accident be followed by a fatal result, its true nature cannot be determined except by an autopsy.

Shively[1] reports an extremely interesting case in which death occurred five or six years after an ovariotomy as the result of obstruction of the bowel, the remote sequence of the fixation of the intestine to the abdominal incision. After the original operation the patient was always "greatly troubled with constipation and frequent attacks of colic." She was obliged to use powerful cathartic pills to keep her bowels open. On August 8, 1883, she was taken ill. "She said she was sick with an attack of colic." August 11th, fecal vomiting occurred and was followed by death. *Post-mortem*—"At the lower end of the line of the belly-cut a discolored spot, half the size of the hand, was seen. The bowel was here adherent. There were also extensive adhesions of the intestines to the sides and posterior wall of the abdomen, thus preventing the appearance of tympany. The intestines and cavity nearly everywhere gave evidence of former inflammation; also a portion of the ileum (eighteen inches above the cecum) was adherent to and incorporated with the cicatrix corresponding to the lower angle of the original wound. Around the short portion between this and the cecum a loop of small intestine was twice twisted, forming a kind of knot and a complete and effectual barrier to the passage of the intestinal contents."

Slipping of a coil of intestine through a slit or aperture. This accident may occur from the following causes: 1. As a result of adhesions. For example, a band of inflammatory lymph may be so attached that an aperture is formed; or, again, a coil of the intestine or the mesentery may adhere and form a loop through which a knuckle of gut may slip. I witnessed an autopsy upon a patient who died after an abdominal section, where the omentum was found adherent to the parietal peritoneum by two distinct attachments, thus forming an opening through which the intestine might readily have passed. An instructive point in this case lies in the fact that the adhesions were caused by two omental stumps, which were left after the omentum had been ligated for adhesions in the course of the operation.

Larkin[1] reports a case in which death resulted from an obstruction following a jejunostomy. The original operation was performed for carcinoma of the stomach, but in less than three months afterward jejunostomy was performed on account of the development of obstructive symptoms. The patient then did well for about two months, when intestinal obstruction again occurred, and death resulted. *Post-mortem:* "There was a firm adhesion between the jejunum and the incision in the abdominal wall made in performing the gastro-enterostomy. The portion of the jejunum taken in the jejunostomy was only two to three inches above this adhesion. The piece of jejunum between these two attachments to the abdominal wall formed a little loop, and between this loop and the parietes the upper segment of the jejunum had slipped. It was firmly nipped. The intestines above were greatly dilated, and ruptured just above the seat of constriction. The intestines below were contracted."

2. From defects in the method of dealing with tears or incisions through the mesentery. Thus, if the mesentery be torn during the separation of adhesions, and the tear is not closed, or its flaps are not well sutured after a resection of the bowel, a coil of intestine is liable to slip into the opening and become nipped. 3. The slipping of a coil of intestine through the vaginal wound, after complete removal of the uterus. 4. A knuckle of gut pushing its way

[1] N. Y. Med. Journ., 1884, vol. xl, p. 292.

[1] London Lancet, 1891, ii, 1222.

through the intestinal loop formed in establishing a lateral anastomosis, without resection. 5. From fixation of the gall-bladder to the abdominal incision. 6. From openings made through the transverse meso-colon and the great omentum, to facilitate the attachment of the bowel to the stomach in performing gastro-enterostomy. In a case of carcinoma of the pylorus in which this was done the post-mortem examination showed that "almost all of the intestines were in front of the great omentum, having prolapsed through a hole in the transverse meso-colon and great omentum. There had passed all of the jejunum and ileum to within four inches of the ileo-cecal valve."

HERNIÆ, OPERATIVE AND INOPERATIVE.[1]

BY THOMAS H. MANLEY, A.M., M.D.,
OF NEW YORK.

As hernial protrusions through the lower abdomen are very common infirmities in civilized human beings, and, as they are always a source of inconvenience and physical discomfort, besides not infrequently endangering life, surgeons, since the earliest times, have actively occupied themselves with most commendable zeal with divers expedients that might effect a radical cure, or to place them in such a position as would conduce to the greatest safety and comfort.

Every sort of mechanical contrivance has been resorted to for the cure of hernia, by the traveling charlatan, as well as by many eminent operators, at one time castration being resorted to, at other times vitriol and caustics, the potential, and others, the steel clamp, suture of gold, "*point doré*," etc. Ségond,[2] in his admirable treatise on hernia, informs us that, for several centuries, various operations for the radical cure of hernia had attained considerable popularity, but all, in time, have fallen into ill-repute and been condemned, to be again revived. From the full and graphic description given by this author we can see that the methods and technique of operation in by-gone times were, indeed, manifold and varied, and that so thoroughly and completely have the ancients gone over the field that but little has remained for moderns to improve on. Hence it is, that the majority of modern hernial operations bearing the names of various surgeons are not new in any sense, but have each and all, with few exceptions, been performed many centuries ago.

The cardinal object in view, in all cases and in all times, has been the same. The most noteworthy characteristic of the attitude of surgeons toward hernial operations has been the tendency to extremes. As recently as twenty years ago the operation for the radical cure of a reducible or incarcerated hernia was not countenanced or permitted. Now, the opposite extreme prevails, not here in America alone, but in all the principal cities of Europe. Every sort of hernia, regardless of condition, situation, age, sex, etc., is regarded as adapted for active surgical intervention. No operation yet devised will, however, always prove curative. Surgical methods will, nevertheless, permanently cure a certain proportion; properly carried out, they will relieve nearly all. In many, an operation will effect no improvement, and in certain non-strangulated herniæ the mortality attending operation will always be great.

With a view of reaching a middle ground, and defining those cases in which surgical operation is justifiable, and discrediting those in which we should refuse to interfere, these notes are written.

A FEW GENERAL CONSIDERATIONS ON OPERATIVE HERNIA.—There are always certain general considerations that must never be lost sight of in all cases. We should possess, as a ground-work, a thorough knowledge of the natural history of hernia, its complications and infinite varieties, of what we expect from Nature's unaided powers, and what benefit we may derive from an intelligent, tentative therapy.

In every case in which a radical cure is undertaken, we must consider well the consequences, for not a few may suffer after operation from a relapsing hernia, which is often much more unmanageable than the primary disorder; we should, besides, invariably warn the patient of this possibility.

Dr. William T. Bull,[1] of New York, in a recent brochure, claimed that relapses are so frequent after surgical management that the term "radical cure" should be abandoned. Paul Ségond, in his work published ten years ago, took a similar position, claiming that any operation may kill—*peut tuer*—and that none is ever justifiable in hernia "except in those in which the dangers from delay are in direct proportion to those entailed by surgical intervention, and then only when all other expedients have failed." Félizet[2] takes an opposite position, though he distinctly avows that the surgeon should never permit himself to be swayed in these cases except from humane impulses and in cases that will yield to none but operative measures. He says: "While anesthetics have rendered the most painful and tedious operations painless, and rigorous antisepsis has made infection impossible, neither has changed the moral of our art; hence the scalpel should be taken up early in hernia, which becomes

[1] Read before the Section on Surgery and Anatomy of the American Medical Association, at Detroit, June 9, 1892.

[2] Félizet: Opér. Herniales chez les Enfants, etc., p. 17.

progressively worse with the advance of age." As all herniæ operated on are radically cured, and several remain permanently so, it seems absurd to ask us to disregard the evidence of our own senses.

No sort of surgical operation can, or ever has, perfectly reconstructed anything. We may relieve a man of a dislocation, fracture, fistula, or stricture, but we have not always removed the causes that led to them or restored anything like perfection. Careful dissection of a hernia will discover defective development; a want of symmetry or uniformity in the anatomic structures in the area of the breach. Hence, he who pretends or claims for any operation, no matter how skillfully performed, that it will ever accomplish anything more than an improvement in the way of confining the viscera, or so placing them that they will give a minimum of inconvenience, trespasses too far on the credulity of his professional brethren, and makes an unsupported assertion.

The radical cure of hernia, then, is an accomplished fact, which must remain, with the same qualifications as when the words *radical cure* are employed in other operations. But, says one, the operation "may kill;" so may the act of vaccination give rise to mortal gangrene or to tetanus, or the extraction of a tooth be attended by instant death. Dr. Bull himself admits that the mortality in operations for radical cure is "practically *nil*." It is interesting to know the present attitude of M. Paul Ségond, after the lapse of ten years[1] (January, 1892). He says: "I now regard the operation for radical cure of hernia an excellent one, and I perform it for every species of the deformity." That the operation for radical cure of hernia has secured for itself a legitimate position in the field of surgery is best attested by the fact that to-day in every civilized country of the world it is being performed on a large scale, with most gratifying results; but it has its limitations. In properly selected cases, it is a veritable boon. These are rare. In many the operation is little better than a barbarous mutilation. It is not, then, in every case a cure-all, but an expedient to be employed only in aggravated cases when other means fail.

Where must the line be drawn between the selected and the rejected? Infantile or congenital hernia is, in the majority of cases, spontaneously curable. Accordingly, only those that increase rapidly in volume, are painful, incoercible, and liable to strangulation, should be operated on. We may examine into the etiologic, anatomic and clinical factors of each, so that a grouping and classification may simplify their study and enable us to reach logical conclusions:

1. Hernia under the tenth year.
2. Hernia in advanced age.
3. Male hernia.
4. Female hernia.
5. Congenital hernia, proper.
6. Acquired hernia, so called.
7. Laparotomy hernia.

REGIONAL DIVISION.

1. Complete inguinal hernia.
2. Incomplete inguinal hernia.
3. Inguinal hernia in the female.
4. Crural hernia in the male.
5. Umbilical hernia in the male.
6. Umbilical hernia in the female.
7. Ventral hernia in both sexes.
8. Obturator, lumbar and perineal hernia.

DIVISION ON A BASIS OF THE MORBID ANATOMY AND PATHOLOGY.

1. Simple hernia in general.
2. Incarcerated hernia.
3. Strangulated hernia.
4. Enterocele.
5. Epiplocele, or entero-epiplocele.
6. Hernia complicated by pathologic changes in the sac.

Infantile hernia is very common in the male sex, and is attributable to a mal-descent of the testis; phimosis; or partial atresia of the urethra. When the testis in its descent contracts adhesions with the omentum or the intestine, and pulls it down into the scrotum, we have the type of hernia designated by *anatomists* congenital; it has no independent peritoneal envelope. This is a stubborn, unyielding type, which no apparatus can cure.

True umbilical hernia is often seen in babies, particularly females. With few exceptions it disappears before the infant walks.

In the inguinal hernia of the female, which cannot be reduced or controlled, a prolapse of the bladder, ovary, or uterus itself, should be carefully looked for. Dr. Barker,[1] of Saginaw, Michigan, has reported a case in which he discovered and removed the uterus in an inguinal hernia in a young woman. Boyer[2] cites the case of a young woman who was impregnated and carried her child to full term in a hernial sac. The same author reports the excision of a six-ounce urinary calculus, through a prolapsed bladder, in an inguinal hernia. I have myself within the past year removed an ovary adherent to an extended intestinal coil in the case of a young lady who had been unavailingly treated by truss-support previously to operation. It was almost needless to say that surgical operation is demanded in all very complicated cases.

[1] De la Valeur de la Cure Rad. des Hernies au Point de Vue du Resultat Definitif.

[1] Am. Journ. Gynecology, Oct., 1891.
[2] Boyer: Malad. Chirurg.

Unless in very exceptional instances, the hernia of the aged should not be interfered with. At this epoch of life, the bloodvessels have taken on degenerative changes, and, besides, the adhesions of the sac with the cord have undergone such fibrous induration that they are separated with great difficulty. Strangulation is an unusual event in very advanced life.

Sexual peculiarities complicate hernial operations. The presence of the spermatic cord is an embarrassing element in the inguinal operation in the male. To so close in the inguinal portals as to prevent relapse, without exercising undue compression on the spermatic vessels, is the ideal to be secured.

HERNIA IN THE FEMALE.—Hernia being less frequent in the female than in the male, we are less concerned with its management; nevertheless, hernia in the female is often painful, and when strangulated, attended with great mortality. The speediest and safest method of relieving it should engage our most serious study.

For anatomic reasons the inguinal type is uncommon in females, crural hernia being quite frequent. Since laparotomy has become a current operation, we are frequently seeing eventrations of the viscera, which make their way through the weakened or separated *fascia propria* into the subcutaneous tissues. When these are discovered, they should be treated by proper pressure-supports; but when they have attained great volume, surgical intervention may be considered.

At a late meeting of the British Medical Association, Lawson Tait described a method of curing hernia by performing laparotomy and reducing the protrusion from within. This is not a bad scheme if a patient has a hernia in connection with an abdominal growth—one taking advantage of the opening to remove the tumor, to introduce the fingers and replace the viscera. Except under these circumstances, it is apparent to every one that this procedure has no place in the surgery of hernia.

CONGENITAL HERNIA.—As a rule, it will be observed, on examining the scrotum at birth, that it is out of proportion in volume to the rest of the body; that there is often a peculiar conical contour of the spermatic cord on one side or the other, giving an impression to the eye and touch of a hernia. My own impression is that in the vast majority of male infants the funicular process is not completely closed for varying periods after birth. In those in whom there are no impediments to the emunctories, or who are not taught to walk too early, it will close during the first year; while on the contrary, when an opposite condition prevails, a hernia may present itself. Nature is generally competent to deal with this state of incomplete evolution. Cases are sometimes encountered, however, in which at birth the hernia is of considerable size, which a truss cannot comfortably control. Opinions are at variance as to the course to pursue with them. My own practice with this class has been to immediately operate and then have the child for a while after wear a truss. I have operated on such a case on the fifteenth day.

ACQUIRED INGUINAL HERNIA, SO CALLED.—Most authors are accustomed to divide the causes of hernia into predisposing and active. My experience has led me to regard hernia of every description as being in every instance an infirmity, invariably attributable to predisposing causes, and to those solely and alone; to congenital or anté-natal conditions, the so-called active cause being but an incident, and nothing more, bearing about the same relation to the hernia that a local injury does to the evolution of a carcinomatous growth. On rigid scrutiny, it will be found that, in the vast majority of cases seen in late life, the patient either had hernia in childhood or had a sense of weakness at the seat of trouble; that it was undiscovered, left alone, or treated by the truss and disappeared long before the child came to the age of reason, and hence he has no recollection of it.

Thomas Bryant, in his excellent *Treatise on Surgery*, tells us that nearly all herniæ disappear before the tenth year; but that many of them return again in adult life. It is very probable that, in many of those cured early in life, only the viscera return, the sac remaining; the neck contracting, so that in the event of a severe strain, when much effort is demanded, the orifice suddenly gives way, the viscera sliding downward into the pouch, which awaits their advent. This makes it clear that, while tentative methods serve a most useful purpose in early life, they do not nevertheless effect an enduring cure, as but part of the hernia is returned.

The treatment of acquired, or rather consecutive inguinal hernia, must be governed by circumstances, whether strangulated, threatened with strangulation, of great volume, complicated, etc. It may be said, however, in a general way, that, when they can be comfortably controlled by a truss, no operation is called for in men. In women, the case is somewhat different, for in them we have no spermatic cord to annoy us, and obliteration of the canal of Nuck is comparatively a simple matter.

LAPAROTOMY HERNIA.—It is said that from 25 to 30 per cent. of women upon whom laparotomy has been performed suffer later from hernia through the line of incision. These cases constitute by all odds the most unmanageable and melancholy phase of the infirmity. Anatomically, they bear a close resemblance to the immense exomphaloceles met with in child-bearing women.

Like the latter, the former have no serous invest-

ment, and tend to constantly increase in size. I have seen the greater part of the floating viscera make their way out of the cavity of the abdomen into one of these adventitious pouches, effecting a practical eventration of the intestinal canal.

Operative interference is not, as a rule, admissible in these huge masses, and should not be performed except in the event of impending strangulation. When we do operate, our interference should be limited to the relief of the constriction, leaving the incarcerated mass in its newly-formed abode.

HERNIA IN THOSE SUFFERING FROM CONSTITUTIONAL DISEASE.—It may be asked if a patient present himself with a painful, incarcerated inguinal hernia, who is suffering from a constitutional disease, are we justified in advising radical measures of relief? It is well known that many chronic maladies run a very long course, and that many pronounced incurable are often recovered from. This is notoriously the case in renal, hepatic, and pulmonary disorders. With these there is no justification, however, for operative interference, except in the presence of desperate symptoms arising through the hernia. It is a curious fact, that I have never met with a painfully complicated hernia in invalids. Certainly, strangulations are very seldom or never met with among them.

REGIONAL DIVISION OF HERNIA. COMPLETE INGUINAL HERNIA.—As the designation indicates, the hernia completely clears the rings and the entire canal.

It would seem that the readjustment of the dislocated viscera, their return by the path that they traversed, and their retention, should not be a difficult undertaking. We may remove the sac, if there is one; approximate the pillars and secure adhesive inflammation. There has, however, been an undue lengthening of the mesenteric ligament; perhaps, there is an excess of intestine; or the peritoneal cavity is intolerant of the returned viscus, when our union of the parts may in a while give way, and down comes the hernia, in a worse position than ever; or as we wall back one, another descends on the other side. This species, the complete inguinal, is the most easily managed of all herniæ. Hence, only in the event of a condition rendering life miserable or endangering it, should we speak of a kelotomy.

INCOMPLETE INGUINAL HERNIA.—This form of hernia seldom gives any trouble, as when its sac has contracted solid adhesions it so firmly blocks the canal that nothing can pass it. Moreover a truss is seldom needed for its support. These bubonoceles, however, may contain within them an undescended testicle or a neoplasm; besides, by pressure on the spermatic vessels, they often induce varix of the spermatic veins or hydrocele, impotence or neuralgia of the testis. Hence, when these sequelæ arise we should not hesitate to operate, though we must not forget that for obvious reasons the permanent results are not always as satisfactory as with other types of hernia.

DIRECT INGUINAL HERNIA.—The diagnosis of direct inguinal hernia is a physical impossibility. True, by the aid of the scalpel and a good light it may be recognized, but not by any other means. My conviction is that it is a very rare pathologic entity. In more than a hundred operations I have met with but one case that I was quite sure was of this type. Indeed, in these old inguinal herniæ, in which the canal becomes obliterated and the hernial rent is simply a large hole in the aponeurotic wall, it is not, by any means, even on dissection, that the precise, original type can always be determied. It is quite impossible. Anatomists will tell us that we should readily discriminate one from the other by their coverings, the relations of the vessels, etc. But in old herniæ we are not dealing with normal structures. Happily, it is of little consequence in treatment, whether we are dealing with the direct or indirect, except in operating for strangulation, when we are warned that, in the direct variety, the mass comes down to the inside of the epigastric artery. Anatomic refinements should not concern us, when we proceed to operate, after proper preparations. As an immense hiatus is left between the pillars after the excision of the tendinous envelope of a direct hernia, a permanent cure will seldom follow the radical operation.

INGUINAL HERNIA IN THE FEMALE.—Inguinal hernia in the female is as rare as femoral hernia in the male. For anatomic reasons already considered, their frequent, painful complications, their simplicity of cure by surgical operation, render them a peculiarly suitable class for radical cure. Dr. Perry Schoonmaker, of New York, recently exhibited an infant a year old which had had unmanageable inguinal hernia. He opened the sac, removed a prolapsed ovary, thereby effecting a permanent cure. To young women about to be married the operation of the radical cure is in every case to be recommended, for the purpose of removing an unsightly blemish and affording security against the dangers of a subsequent strangulation.

CRURAL HERNIA IN THE FEMALE AND IN THE MALE.—When we carefully study the anatomy of crural hernia in the female we can appreciate the many difficulties in the way of rendering permanent a radical cure. Hence it is that it is only with the minority of them that sanguineous methods should be invoked. The great barriers in the way are the blood-trunks of the lower extremity that occupy the femoral arcade. Their periodic enlargement in the child-bearing woman, with the possibility of

dangerous compression through the cicatricial contraction after incision, usually interdicts any attempt in the way of radical cure. Truss-support is preferable in all simple, uncomplicated cases of femoral hernia in the female. We must be guided by the same general principles here as in the crural hernia of the male, though it should be noted that owing to the diversity of function in the female, the prospects of a permanent cure following operation in the male are better than with her.

Umbilical Hernia, Exomphalocele, Median-Ventral Hernia.—Umbilical and median-ventral herniæ are not very uncommon in child-bearing women. It is unnecessary to remark that the umbilical hernia of nursing infants rarely requires any special treatment.

If in women these herniæ attain a great volume, or if their overlying tunics ulcerate, giving rise to much pain and often to free hemorrhage, they become a very troublesome condition to manage. Fortunately the greater part of those of massive size seldom occasion much inconvenience, except by their weight.

Anatomically, but few of these extrusions can be regarded as genuine exomphaloceles, for their escape is but rarely through the unclosed umbilical ring, but rather on either side, above or below it. For this reason it is unusual to find the round ligament of the liver or the urachus prolapsed with them. This type of hernia has no independent sac; hence, as it escapes from the abdomen, the viscera wander in every direction and form intimate adhesions with everything with which they come in contact, so that their vascular supply is ultimately rather from the vessels in the tissues in which they are recently lodged, than through the mesenteric trunks. As, owing to their volume, their state of incarceration and convenient proximity to the solar plexus, the complete removal of these herniæ is a procedure attended with a great mortality, none but those presenting symptoms of strangulation or those that consist of omentum alone, are appropriate for operation. In all cases of sudden intestinal obstruction, the navel should be carefully examined for hernia.

Strangulated Hernia.—In the majority of cases, perhaps, strangulated hernia may be reduced by taxis. It would seem, however, that in our time, when it can be radically cured by an operation attended with little or no danger to life, when performed early, every case of this description should be promptly operated on. In those suffering from renal or pulmonary disease, we may, in all cases, substitute cocaine analgesia for pulmonary anesthesia. This I have repeatedly demonstrated with most gratifying results.

Incarcerated Hernia.—The morbid anatomy of incarcerated hernia furnishes us with an excellent illustration of the very best work that unaided Nature can perform in the way of protecting an organ against an accident which an imperfection or incompleteness in her own processes has caused.

An incarcerated hernia maintains an independent existence, mainly drawing its sustenance from extraneous parts. Those of minor dimensions and devoid of painful complication should not be disturbed, unless they show a tendency to increase in size, when a truss may be worn. With the larger and more ungovernable variety, with occasional symptoms of obstruction, we must interfere, but only when other measures of relief have failed.

Epiplocele.—An epiplocele, a purely omental hernia, is that variety which always offers the best prospects of cure by operation; for, by the excision of the adipose tissue the cause of the tumor is removed and intra-abdominal pressure is not increased. I have never seen a relapse after operation on this class, and believe in general, that unless there be some complication, they should always be dealt with by radical measures.

A CASE OF CIRCINATE PAPULO-ERYTHEMATOUS SYPHILIDE WITH PSORIASIS PALMARIS SYPHILITICA.[1]

By G. FRANK LYDSTON, M.D.,
OF CHICAGO,
PROFESSOR OF THE SURGICAL DISEASES OF THE GENITO-URINARY ORGANS AND SYPHILOLOGY IN THE CHICAGO COLLEGE OF PHYSICIANS AND SURGEONS.

Numerous observers have directed attention to a comparatively exceptional variety of papular syphiloderm, occurring in the secondary periods of syphilis, which assumes a form always closely resembling, and frequently precisely identical with, ordinary tinea circinata. Several beautiful examples of this form of eruption have come under my observation, the case shortly to be described being the most typical and clearly outlined of any that I have seen. One of the first cases that I encountered in private practice occurred in a young man who presented himself for treatment for several patches of what appeared to be ordinary ringworm, one of which was located upon the right cheek, and the other upon the opposite side on the neck. Decided pigmentation of these patches made me at once suspect that they were syphilitic, and I therefore made a careful general examination, with the result of discovering general lymphatic engorgement, a characteristic sore-throat and several mucous patches upon the tongue. Upon the roof of the mouth were several distinctly circinate, elevated, reddish patches, one of which presented the arc of a circle representing about one-half the size of a silver

[1] Read in the Section on Dermatology and Syphilography of the American Medical Association, June 9, 1892.

quarter; the other, a perfect circle, of the size of a silver dime. The borders of these circular patches were elevated and of a brighter red color than the normal mucous membrane. The center of the patches was normal or nearly so, the membrane possibly being rather paler than usual. The subsequent history of the case and its behavior under treatment confirmed the original diagnosis of circinate syphilide.

The case at present under consideration is a very interesting one, in that we have two varieties of lesions representing two different stages of syphilis and occurring within a short time after the inception of the disease.

The patient, a woman, twenty-four years of age, presented herself at my clinic at the suggestion of one of my brother-physicians. Four months before coming under my observation, she contracted a chancre. This was followed by a bubo and, in

FIG. 1.

about two months, by what, from her description, was evidently a roseola, interspersed with distinct papular syphilodermata. The first generalized eruption had, according to her story, disappeared, with the exception of some of the papules upon the face and upon the palms of the hands. These lesions had not only persisted, but had increased in number and prominence. Shortly after the appearance of the first euption, several mucous patches in the mouth, and sore-throat developed. The woman had drunk considerably and admitted the cigarette-habit, this circumstance amply explaining the obstinacy of the lesions under treatment and the persistence and severity of the lesions of the mucous membrane of the mouth and throat. There had been, she stated, considerable falling of the hair. Within three or four weeks prior to appearing at the clinic the woman stated that there had developed a generalized eruption on the face, which she thought was erysipelas, and which she feared would extend all over the face. On examining the patient, I found upon the face a number of distinct, circinate papular syphilodermata of varying size and form. Some of these presented the form of distinct circles; others were more or less crescentic in shape, and several of them were fused together somewhat like a figure 8. Upon the back of the neck, just at the roots of the hair, there were two quite large crescentic-shaped lesions, one of which was nearly as large as half the circumference of a silver dollar.

FIG. 2.

Upon each side of the face, beginning in front of the ear, which it involved, was a syphilide considerably larger than a silver half-dollar, the periphery of which was distinctly raised, the center being perfectly healthy. A peculiar feature of these syphilides was the symmetry and their conformation in a general way to the outline of the ear itself. The elevated portions of all of these lesions were more or less scaly. The nose, upper lip and chin were the seat of erythema, with abrupt edges, slightly, if at all, elevated above the surrounding skin. This erythema underlay a number of the circinate syphilides and extended out upon the cheeks and upwards over the eyebrows for a short distance. This erythema does not, I regret to say, show in the appended illustration. The

mouth and throat were decidedly involved. The soft palate presented a distinctly circinate patch; the fauces were congested, and upon the right side an ulcerating mucous patch was observed. The tongue was the seat of several inflamed mucous patches. There was pronounced syphilitic adenopathy. The palms of the hands presented as fine an example of psoriasis syphilitica as one would care to see. This psoriatic eruption, as will be seen by the appended illustrations, was quite extensive and plainly marked. Under rigorous mercurial treatment, with regulation of the patient's habits, with local applications of mercuric chloride and tincture of benzoin, the facial eruption was speedily removed; that upon the palms was quite stubborn, persisting for several weeks after the erythema and circinate lesions had practically disappeared.

The circinate papular syphilide has been described as syphiloderma papulosum circinatum by Dr. George H. Fox[1] and Dr. I. E. Atkinson.[2] Jullien[3] describes it as *syphilide en cocarde*. Kaposi[4] also describes *syphilis cutanea*. Bumstead and Taylor[5] have described a flat variety of the papular syphiloderm, which becomes elevated as a distinct ridge at the periphery or as an annular crest, of a dull yellowish color, at the periphery of an ordinary papule. These authorities also state that as papules retrogress, especially in late syphilis, the center of the lesion may be absorbed first, leaving a more or less scaly ring, which is itself firmly absorbed.

Professor Atkinson's paper is illustrated by a beautiful example of the disease, occurring in a young negress, and is one of the clearest and most accurate descriptions of this peculiar form of syphiloderm. To this paper I am chiefly indebted for the description of the lesions.

Atkinson states that the lesions of syphiloderma papulosum circinatum develop esssentially from the annular or circinate arrangement of the papulo-tuberculous lesions, so frequently seen upon the skin in late secondary and tertiary syphilis, each group representing a number of distinct and separate lines arranged in a circular form; whereas the circinate papulo-syphiloderm invariably begins in a single lesion (a papule), from which the lesion spreads as the primary papule itself disappears. Dr. Atkinson has had exceptional opportunities for observing negro patients, and states that this peculiar syphilide is especially frequent in them. I have had no opportunities to form an independent opinion upon this subject. Atkinson's description is as follows:

"In its milder and more limited development it affects preferably the face and neck, but when extensive, no part seems to escape it: back, breast, belly, thighs, arms, hands become invaded. Where the onset is acute and the eruption copious, fever may be present, and the lesions may form with almost the rapidity of those of the eruptive fevers. The lesions appear as bright or dusky-red discs, but little elevated in comparison to their breadth, and varying in size from that of a small pea to a diameter of two centimeters and more. Some remain without further development, or within two or three days begin to desquamate in thin, fine scales, beginning at their peripheries. This desquamation exposes either a dry, smooth, reddened, and flattened elevation, or a moist surface which speedily forms a thin straw-colored or brownish scab, flattened and depressed toward the center. After some days, these scabs fall off and leave pigmented spots. While these changes are going on in some lesions, others exhibit a more curious but less intense activity. While the peripheries of these papules show a scanty, fine desquamation, their central portions gradually sink down to the level of normal skin, and their borders extend centrifugally. A short interval suffices to convert the former papules into unelevated central areas, surrounded by narrow but abrupt borders of elevation, forming continuous rings of infiltration and continually throwing off fine scales. Rarely, the eruption may be limited to a half-dozen of these spots, irregularly scattered over the face, neck and shoulders.

"The color of the central area will now be of a dusky-red color, slowly fading to a duller hue; while the border will be of a darker and more characteristic tint. The central area now continues to grow larger, and by the extension of the slightly elevated border, all resemblance to the original papular lesion is lost. Instead, there is presented an appearance strongly suggestive of severe tinea circinata, which, indeed, it may so closely simulate that, without the previous knowledge of the patient's syphilis, the lesion may, upon superficial examination, be mistaken for ringworm. The elevated border will present a continuous narrow line of a slightly beaded appearance, and will throw off a fine branny desquamation. The central portion of the patch will usually resume its normal surface and thickness, but there will remain the deeper pigmentation; while its size will increase, and its shape will undergo modifications, altering the originally circular outline. In negroes, the ordinary pigmentation of the patches will be replaced by a simple increased intensity in the normal darkness of the skin.

"These patches may reach a diameter equal to that of a half-dollar, and by the confluence of several, great irregularity of extent and outline may be attained. I have never seen any patch larger than the size just mentioned, nor do I know to what extent they may proceed if uninfluenced by treatment. It is likely, however, that spontaneous involution would destroy the patch before a much larger extent could be gained. In many patches a curious recrudescence occurs in their centers, whereby a new papule forms, and immediately proceeds to follow the course of its predecessor in extending periphe-

rally, though, it is true, the extending border rarely forms a complete circle, but rather a segment of greater or less size, and not so sharply defined as the first one. Sometimes a third papule may develop within the pigmented inclosed space, and proceed to extend in the same centrifugal manner.

"But small provocation is required to convert these lesions into mucous patches, and when the axillæ or groins are invaded they readily become such. In a young woman, a negress, syphilitic eighteen months, the papular circinate syphiloderm developed within the buccal cavity, where the lesions, immediately becoming mucous patches, adopted the centrifugal extension, the narrow border assuming a pale, opaline aspect. Unlike the usual course of syphilitic cutaneous eruptions, this form, more especially when the rapid and excessive exfoliation of the epidermis lays bare the cells of the Malpighian layer, with the result of forming thin peripheral or general crusts, is often accompanied by a considerable amount of itching, as may be seen from the scratch-marks often present."

Perhaps the most interesting feature of my own case is the association of the circinate syphilide of the face and neck with the papulo-squamous syphilide of the palms of the hands, popularly known as *psoriasis palmaris syphilitica*. Such papulo-erythematous lesions as have been described are characteristic of the secondary period of the disease and may come on early; whereas the palmar syphilide, as seen in this case, usually occurs either in the period of sequelæ or as a late secondary manifestation. The condition illustrated is more marked than is the ordinary papular syphilide of the early stages of the disease, and it is much more obstinate to treatment. While, in the case at present under consideration, the lesions of the palms yielded comparatively easily to specific treatment, they were very much more tardy in disappearing than were the lesions of the face. They left, moreover, an erythematous surface corresponding in area and form with the original lesion, and relapse occurred within two or three months after the infiltration of the skin had completely disappeared, as a consequence of dissipation and negligence on part of the patient. The rule that the circinate syphilide occurs in the early period of syphilis is not without exceptions.

Brauman[1] has called attention to numerous observations that show that in the so-called tertiary period of syphilis there may appear eruptions unlike most tertiary lesions, which are deeply situated in the skin (tuberculo-gumma syphilides), in that they present a superficial character and may closely resemble the syphilides of the secondary period. These superficial eruptions of the tertiary period present themselves in two forms, viz., a superficial papular eruption, which is most exceptional, and an erythematous eruption of a pale-rose color, a little yellowish in parts, forming large circles, or more frequently lesions of an oval or elliptical form. To the latter form of eruption has been given the name *erythème circine tertiaire*. This resembles a late roseola of the circinate form that has been called by Fournier *roséole de retour* and which may appear very late in secondary syphilis. This late roseola seems to establish the pathologic connection between the roseola occurring at the beginning of the secondary period and the peculiar circinate erythema of the so-called tertiary stage of the disease. In the superficial eruption described by Brauman, the lesion almost always presents itself as a simple erythema, without elevation, and there may exist a certain amount of desquamation of the very fine scales which tends to be very stubborn, even if well treated, and yields best to the mixed treatment.

Cases such as my own show that a distinct erythema more or less generalized, *i. e.* extending uniformly over quite an area of the skin, may be associated with distinct lesions of the syphiloderma papulosum circinatum. This case also shows something of a tendency to precocity, incidental, I presume, to the bad personal hygiene of the patient.

ORIGINAL ADDRESS.

THE NECESSITY AND THE BEST METHOD OF REGULATING THE PRACTICE OF MEDICINE.[1]

BY PERRY H. MILLARD, M.D.,
HONORARY MEMBER OF THE AMERICAN ACADEMY OF MEDICINE, DEAN AND PROFESSOR OF THE PRINCIPLES OF SURGERY AND MEDICAL JURISPRUDENCE, UNIVERSITY OF MINNESOTA.

IN reviewing the question of medical education in the United States the student of history will readily conclude that the facilities afforded pupils of medicine have been painfully inadequate, and that the minimum of requirements in a vast majority of colleges has been well below that standard which affords the public a profession possessing a degree of skill and ability commensurate with the safety of its people. It has been the policy of the authorities controlling these institutions of learning to maintain a standard below recognized safety. In addition to the very low curriculum, the resources of most colleges have been inadequate, and the clinical instruction most deficient. It is but recently that a majority of the colleges in this country have attempted a system of regular laboratory instruction. The causes leading to this dilemma are many; among the most common may be mentioned:

[1] Read at the Seventeenth Annual Session of the American Academy of Medicine, June 6, 1892.

First. The history of pretended medical education in this country covers a period of little more than a century, the people possessing those elements of hurry and restlessness observed in all new communities.

Second. It has not been the policy of this government to liberally support university or higher education—a form of education reaching a high degree of perfection in the British Isles and Continental Europe, and embracing in its scope all special lines of advanced instruction, such as law and medicine.

Third. The people being governed by a republican form of government, the policy has naturally been liberal in respect to freedom of action and choice of avocation; not infrequently this policy has been at a sacrifice of the best interests of a credulous public. In a monarchical or patriarchal form of government it is much easier to restrict or control the action of the people.

Fourth. In consequence of the late civil war, covering a period of four years, a half-million young men found themselves penniless, with limited education and without avocation or profession. Many thousands had secured a superficial knowledge of the art of medicine and surgery from their war experience, and naturally, as a result, a horde of brave but uncultured men turned their attention to the profession of medicine. In consequence, the number of medical colleges in the United States doubled in a short period of time, and the list of matriculates increased at a much greater ratio. Notwithstanding the wonderful increase in population and resources of this country, in a period of a few years the proportion of physicians increased far beyond the legitimate demands of the public.

Fifth. There has been a noticeable absence of that concert of action so necessary between the different schools of instruction to secure uniformity of system in education, or uniformity in the attempts at the elevation of the standard of medical instruction. There has been no restriction to the unlimited multiplication of the number of medical colleges. There has been no attempt to dictate the character of instruction by legislative control. There has been but little attempt to regulate the character of instruction even by the faculties themselves. In consequence, the profession and the public have in the last few years been casting about for a means of remedy to avert a disaster that seemed to imperil the very existence of the noblest of the learned professions. It became apparent to the observing and thinking that the profession of medicine was being degraded in its *personnel*, and but little respected by the people themselves. A condition was fast approaching whereby we were placed in quite as ridiculous a position as is described by Molière in the fourteenth century. It required but a casual study of the situation at that time to conclude that but one of two methods was available for the correction of the existing evil. The first was that the power to raise the standard of medical education in the United States was vested wholly in the various faculties of medical instruction, and by concerted and business-like action they could readily comply with the most reasonable demands of the profession and the public, and, in doing so, not materially injure their own interests in bringing about the much-needed reform.

The second was that in failure thereof the only alternative was a resort to some restrictive legislation compelling the various colleges to raise their standard of instruction, as applying both to the preliminary entrance examination and to the curriculum of professional duty. A sincere attempt was made by representatives of a few colleges in a period of time from 1876 to 1882, and there resulted from this effort the lamentable history of the American Medical College Association. The disruption of this association was brought about by the treachery of a few representatives of colleges whose policy was governed entirely upon a commercial basis. The disruption of this association at the time was considered a great professional calamity, and the friends of higher medical education soon cast about for some method of bringing order out of chaos.

It was determined that the best means of controlling this evil was through efficient medical legislation. As a result, members of the profession scattered throughout different portions of the country attempted to secure legislative enactments creating State boards of medical examiners. In a majority of instances the attempts were met with defeat at the hands of the different Legislatures, and a majority of the bills that had become laws were painfully defective, as could only be expected in any new form of legislation. The first acts that were recognized as efficient, and at all restrictive, were those of the States of Illinois and West Virginia. Immediately following we have substantially the same act in force in the States of Missouri, Iowa, Minnesota and Dakota.

This form of legislation permitted men to become legal practitioners by submitting a diploma issued by a regularly chartered medical institution. The act further provided that diplomas may be refused or revoked for unprofessional or dishonorable conduct.

The profession soon recognized and became convinced that the so-called Illinois act, if properly enforced, would exercise a wholesome and restraining influence upon medical colleges and rid the public of the infamous practices of the itinerant charlatan. Those of us whose painful duty it was to enforce

the medical law referred to know too well the herculean task we had undertaken. The barriers seemed insurmountable, and our only solace was the realization that our cause was just.

It was my province to act as Secretary of the Minnesota Board for a period of five years, or during the life of the first Practice Act. This act was substantially a copy of the act now in force in the State of Illinois and several other States.

My experience and observation soon convinced me that we had upon our list of recognized colleges a large number of schools whose alumni were not safe practitioners. Any attempt to discipline these institutions was met in a most belligerent spirit, or by an influence well suited to the ward politician or political blackmailer.

I became firmly convinced that the principle of recogizing the diplomas of colleges was not the correct one. I soon agitated the propriety of the amendment or entire repeal of the Minnesota act, or the securing of a new act calling for a personal examination of each and every person wishing to practise medicine in the Commonwealth. The propriety of determining the fitness of men to practise medicine by means of a personal examination was recognized and acknowledged to be the proper method by the State Board of Minnesota. At a conference of Boards of Medical Examiners held in Chicago in 1885, I urged the propriety of concerted action in an attempt to secure uniformity of legislation by an act in the several States calling for an examination of each candidate for a license, and providing, as in the Illinois act, the privilege of refusing or revoking licenses for unprofessional or dishonorable conduct. The consensus of opinion at this conference plainly indicated that it would be a step in advance if we possessed legislation granting the privilege of examining all students wishing to commence the practice of medicine. The majority of those present, however, were of the opinion that the opposition would be so pronounced as to insure defeat. The members of the Minnesota Board, however, concluded to ask the Legislature for further legislation, and I was instructed to draft a bill for submission at the forthcoming session. The bill was the same as the one now in force in Minnesota and several other States. It became operative with us July 1, 1887. It established a minimum of time to be spent at medical lectures before a person would be permitted to apply for an examination to determine his fitness to practise medicine. It further provided for an examination of all persons wishing to commence the practice of medicine in any of its branches in the State. It likewise granted the privilege to refuse or revoke licenses for unprofessional or dishonorable conduct.

It was the first draft of a bill to become a law that called for a minimum of time to be spent at lectures before commencing the practice of medicine. This feature of the bill has proved eminently satisfactory in Minnesota, and has been copied in the statutes of several other States. Its effect has been most salutary upon several of the medical colleges of this country, and, as a result thereof, nearly every institution of this country whose term of lectures was less than six months has extended its duration to comply with the statutory requirements of the several States. At the present time, persons wishing to commence the practice of medicine in the following named States are required to prove their fitness therefor by undergoing an examination: Minnesota, North Dakota, Montana, Washington, North Carolina, Alabama, Florida, Virginia, New Jersey, New York, Nebraska, Maryland, and Utah.

Nearly all of this legislation has been accomplished in the period of the last five years, and the present indications are that in the near future a majority of the States of the Union will secure correspondingly adequate legislation. The agitation of this reform has met with quite bitter opposition from some sources—the principal opposition, however, coming from the authorities of the various medical colleges. This opposition has been most futile, as the situation of the profession in this country was readily recognized by the legislator, and the further fact that no rational argument could be rendered against the constitutionality or propriety of some form of restrictive legislation.

The necessity of restricting the practice of medicine has been recognized by all nations of civilized people from time immemorial. Every European country possesses most stringent Practice Acts, and has for centuries. The so-called police power has likewise been recognized for centuries.

Traces of forensic and State medicine are as old as institutions of civil society. The Jews recognized mortal wounds. The Egyptians provided that no woman pregnant with child should suffer afflictive punishment. The Romans, even from the period of Numa, grounded many of their laws upon the authority of physicians. The Carolina Code, under Charles V., was established in 1532. The first traces of the exercise of police power as applied to the practice of medicine are found in Italy in 1237. Here a license to practice was granted by the University of Salino after a study of philosophy for a period of three years and of medicine for a period of five years. This license was only obtainable after a satisfactory examination. Shortly after this date licenses were likewise granted in England.

The first degrees in medicine were presumably granted in 1384. The first efficient law regulating the practice of medicine in England was enacted in 1511. The progress of medicine during the seven-

teenth century has been ably described by Macaulay in Vol. I, page 310 of his History.

"Medicine," he says, "which in France was still in abject bondage and afforded for Molière an inexhaustible subject of just ridicule, had in England become an experimental and progressive science, and every day had made some new advance in defiance of Hippocrates and Galen. The attention of speculative men had for the first time been directed to the subject of sanitary police." Investigation reveals the fact that efficient regulation of medical practice and higher medical education progressed, hand in hand, from the period of time mentioned by Macaulay down to the present time. The courts have universally affirmed the legality or constitutionality of the various laws regulating the practice of medicine in the different countries of Europe. The United States Supreme Court has recently rendered a decision affirming the constitutionality and the general features of Medical Practice Acts. A large number of the Supreme Courts of the different States have likewise affirmed the constitutionality of the different Medical Practice Acts. In a few instances, in the lower courts, where decisions have emasculated the power of State Boards of Medical Examiners, it has been due to the faulty wording of the act itself, rather than to any unconstitutional features that may be found in this form of legislation.

In a paper read by me at the session of the American Medical Association in 1888 I advocated a greater uniformity of medical legislation by the various States. The discussion led to the appointing of a committee with instructions to formulate the general features of a Practice Act that would be suitable for adoption in any of the different States of the Union. As chairman of that committee, at the next session of the Association I submitted the draft of a bill possessing the essential features of the act now in force in the State of Minnesota. The report of the committee was unanimously accepted and adopted, together with resolutions urging upon the profession the propriety of at once attempting the establishment of efficient Medical Practice Acts in the different States of the Union. I am gratified to observe that in nearly all instances in which Medical Practice Acts have recently been obtained the essential features of the Minnesota act have been adopted.

The question of medical legislation should be considered from two standpoints, to-wit: That of the regulation of medical practice, and that of the regulation of medical education. In the performance of the first function, boards should consider that it is simply their duty to protect the public from the imposition of charlatans and the grave errors certain to arise from the practices of uneducated men. The duties of the State Licensing Board end here. If the act is so worded as to likewise regulate medical education in the Commonwealth, it is eminently proper that a minimum of requirements should be established, and the Boards authorized to exercise a general supervision pertaining to the character of instruction in all colleges whose alumni become applicants for the privilege of practising in the State. I sincerely question the propriety of one Board performing both of these duties. Basing my opinion upon extensive observation and experience, I believe that the best interests of the public will be subserved by assigning the duties of the State licensing power to the various State Boards of Health.

The medical licensing power is purely a police power, and were these duties assigned to Boards of Health it would assure greater prestige and influence in the community. I believe that the regulation of all forms of education should be vested in a central power, consisting of a single board to be known as a State Bureau of Education, with power to regulate all educational institutions granting degrees, together with the power of granting and revoking charters; particularly should this apply to all institutions wishing to afford the community any of the various forms of higher or special education. Under existing circumstances, in a vast majority of the States of this country, three or more persons can form a corporation, and become incorporated by application to the Secretary of State, and grant degrees *ad libitum*. The *personnel* of these Boards is immaterial, providing the parties be reputable and intelligent practitioners of medicine. It is my opinon that the mixed boards, such as exist in Minnesota, Illinois, Iowa, Montana, Missouri, North Dakota, and several other States of the Union, render better service to the public than the few separate boards that have been created in compliance with the demands of the several so-called schools of practice. In the States possessing mixed boards that conscientiously perform the duties of a public servant I have yet to hear of any clashing or jealousy among the members. I believe the best interests of the people will be subserved by the maintenance of a clause in each of these acts providing for the refusal or revocation of a license to practise, in case of unprofessional or dishonorable conduct. I question the propriety, however, of boards exercising this power except in most flagrant cases.

If John Smith is disposed to occupy the first page of a newspaper in calling the attention of the public to the fact that he confines his attention entirely to diseases of the genito-urinary organs, I believe this indiscretion alone should not cost him the right to practise medicine; upon the contrary, should he

claim in the public press that he can cure what is recognized by the profession as an incurable disease, such as tuberculosis or carcinoma, it is the duty of the board to step in between the credulous public and the dishonorable practitioner and deprive the impostor of his professional rights. It is, likewise, the duty of the board to refuse or revoke the license for persistent and chronic inebriety, criminal abortion and repeated gross immoralities.

As honorable and intelligent physicians, we recognize the great sin of advertising in any manner. In view, however, of the outspoken sentiment in favor of any restriction in this direction, I presume it is better to allow the fool his course, at least until he reaches that point in his career that his practices imperil the safety of the public.

I am pleased to submit some statistics of the work accomplished by several State Boards of Medical Examiners. My statistics are from States where the law requires a personal examination of the applicant's fitness to practise. These examinations include all of the essential branches of the field of medicine. They afford a most convincing argument in behalf of efficient medical legislation.

I trust I may not be considered presumptuous if I assert that in the administration of their delicate and untried trusts it has been the policy of these boards to be somewhat lenient, and to license many whom they knew possessed inadequate instruction. A part of their duties has been to educate both the profession and the public to the propriety of this form of legislation. Notwithstanding this policy, we are informed that 24.8 per cent. of all applicants for a license to practise have been rejected as unsafe practitioners.

My statistics are based upon returns from the following-named States: Alabama, North Dakota, North Carolina, Virginia and Minnesota.

The total number examined was 1950.

The total number classified was 1746.

The total number unclassified was 204. The unclassified represents foreign and extinct colleges and undergraduates.

The total percentage licensed was 75.2 per cent.

Of 183 graduates of colleges requiring three courses of instruction for the degree of M.D., 179 passed examinations; 4 were rejected: making the percentage passed 97.2.

Of 435 graduates of colleges that formerly issued degrees after attendance upon two courses of lectures, 343 passed examinations; 92 were rejected. The percentage passed was 78.8.

The foregoing data are compiled from the records of the different Boards of Examiners. The comparison indicates the results of the examinations of graduates of the graded three-course institutions and those that previously to 1890 conferred degrees after attendance upon two courses of instruction. Colleges were selected that were indicated by the report of the Illinois Board of Health as matriculating respectively the greatest number of students in the year 1890.

The foregoing statistics indicate that graduates of the three-course graded colleges rarely fail before the various State Boards of Medical Examiners.

The practice of medicine is fairly well regulated at the present time in about one-half of the States. The present indications are that the spirit of reform will extend, and in the near future include all of the States. The friends of medical legislation include the masses of the profession and the representatives of the better colleges of the country. Its enemies principally include the representatives of those colleges governed by commercial interests and charlatans.

Up to the present time the number of medical colleges has increased out of all proportion to the increase of population. Of 130 schools, less than a dozen are endowed. The number of practitioners is greatly in excess of the legitimate demands of the people. We are reliably informed that in the decade ending with the year 1890 the colleges of the United States matriculated 115,355 students, and graduated 39,996. This is an average of 4000 yearly—in my opinion, more than twice as many as the requirements of the people demand.

As a final argument in behalf of adequate medical legislation, I beg to submit the following statistics, based upon the proportion of physicians to the inhabitants in a few of the European countries:

RATIO OF PHYSICIANS TO POPULATION.

Sweden,	1 to 7000 population.
Italy,	1 to 3500 "
Germany,	1 to 3000 "
Austria-Hungary,	1 to 2400 "
France,	1 to 2000 "
United States,	1 to 600 "

The foregoing figures explain themselves, and comment seems unnecessary.

Basing my opinion upon observation of the workings of the Minnesota law in its first five years' experience, I am fully satisfied that efficient legislation will reduce the number of physicians to a number commensurate with the needs of the people, and that the people will be better and more honestly served. Minnesota has a smaller number of physicians to the inhabitants than any State of the Union; St. Paul a smaller number to the inhabitants than any of the larger cities of the United States. The result in this State is wholly due to efficient legislation, and the effect of the act has

been to enhance the welfare of both the profession and the public.

Briefly, my conclusions upon the question of medical legislation can be summarized as follows:

1. The regulation of medical practice and medical education is constitutional, and the demands therefor imperative. Secondly, a distinct line of demarcation should exist between the so-called licensing power and the regulation of medical education. Thirdly, the licensing power should include in every State the following essentials:

a. The evidence of the candidate's fitness to practise medicine should be established by his undergoing an examination upon all the important branches of medicine.

b. There is absolutely no necessity for a series of questions that in the least conflict with the views of the various so-called schools of practice.

c. Power should be granted to revoke or refuse license for unprofessional or dishonorable conduct.

d. The exercise of this power upon the part of the different boards should only be resorted to in palpably flagrant cases.

e. The public interests will be best subserved by so-called mixed boards.

f. The power vested is best executed by the State Sanitary Police, or rather the different State Boards of Health.

g. The duties of the act belong to that department of law known as the State Police Power; the appointing power should be vested in the Governor.

h. Appointees should be men of recognized ability and standing in the various communities.

4. I am satisfied that the influences of efficient medical legislation will have a most salutary effect upon the character of instruction afforded students of medicine in this country, and that the faculties of the various colleges in the future will not be so notoriously lax in regard to the conferring of degrees.

5. It is likewise essential that medical education should be restricted or regulated in the various States, and, in my opinion, there should be created a central authority, consisting of a Bureau of Education; this bureau should have power to refuse or revoke charters, and should exercise a restrictive influence as to the character of education conferred, and the authority should apply particularly to special schools of education, such as law and medicine.

6. This bureau should establish regulations pertaining to the granting of charters to medical colleges. The charters should not be granted unless all necessary laboratories are thoroughly equipped; unless facilities for clinical instruction are unquestioned, and unless applicants for charters should satisfy the bureau of their undoubted ability to support the institution financially, without being dependent upon the fees of its students for its sustenance.

In a recent report, the Commissioner of Education of the United States forcibly directs the attention of the public to the inadequate equipment of the medical colleges of this country. We are informed in this report that there are $2,672,000 invested in grounds, buildings, and apparatus for the medical schools of the United States. The amount of productive funds for these schools is only $266,190, and the annual income from investment only $22,000. He states: "When we examine the facilities and demands of this country, with those of the British Isles and Continental Europe, we necessarily conclude that the foreign schools exact too much or that our system is painfully crude and lax." The Commissioner of Education further remarks: "That, considering the enormous amount of knowledge that has been accumulated respecting the proper treatment of disease, its prevention, and its nature, the impression becomes irresistible that we have been influenced by our national impatience and haste in this matter, as well as in many others, and that we have allowed the student to dictate the length of time of study instead of obliging him to spend enough time to receive it properly and retain it securely."

Applied to the profession of medicine, there is but one inference to draw from the foregoing data: we can only conclude that the facilities for securing a thorough medical education in this country are indeed inadequate. The present high character of the masses of the profession in the United States is not so much due to the facilities of college training, as to the individual character of the profession. The vast majority of the profession of this country now in practice received their degrees of M.D. after attendance upon but two courses of medical instruction, of not more than twenty weeks' duration each; many look back upon their medical college career as an unimportant epoch, and think of those days as a work of confusion. The instruction afforded by this system of medical education was hurried, superficial and most inadequate to our wants, the course consisting rather in calling the attention of the student to the art of medicine, instead of teaching him the sound principles upon which is governed the great field of active practice. This system of instruction was a delusion. Our experience confirms us in the opinion that if the student does not become grounded in the essential principles of medicine in his college days, he never will. Except in a few rare instances, a physician does not acquire histology, anatomy, and physiology, and chemistry after receiving his degree of M.D. The few that have become proficient in

later professional life have been placed at a very great disadvantage.

We are pleased to observe at this time a disposition to foster and support a higher system of education among the masses. The present disposition in the various States of the Union is toward a complete divorcement of the public-school system from church or other influences, and affording to the public a system of education fully equal in quality and as extensive in scope as can be obtained in any civilized country. This disposition is particularly noticeable in several of our Western States. We see here millions of dollars spent annually in the support of university education, and the facilities for instruction in several of these institutions are quite unsurpassed. We already have our University of Michigan, with its 2800 students; the University of Minnesota, with its 1400 students, and, closely following, those of Wisconsin, Iowa, Texas, and Nebraska.

The growing tendency of the State to foster higher education carries with it much encouragement for the profession of Medicine. It means a medical department in connection with many of these institutions that are independent and directly supported by the State. I am pleased to see a disposition in many of our colleges to connect themselves with universities. A medical college connected with a university has few objections and many advantages. As we pass the fourth centennial epoch in our history, we can look forward with most sanguine expectations in all that pertains to medicine. We invite our critics to forget the past and only look to the present and future. Present appearances plainly indicate that we are on the eve of a new departure in medical education in this country. The older system of medical education is a thing of the past; let us forget it quickly and look with sanguine expectations to the future.

In conclusion, I again appeal to the profession of this country, and particularly to you, gentlemen—the most intelligent representatives of the profession of medicine in America—to renew your zeal and continue in your efforts until the battle for higher medical education in America is actually won and the good name of the profession of medicine rescued from disgrace.

CLINICAL MEMORANDA.

RÖTHELN.

By S. P. HARRINGTON, M.D.,
of Farley, Mo.

I am prompted by reading the articles regarding scarlatina and Röthlen that have appeared in The News to present a report of twenty cases of Rötheln, some of which if isolated would have been hard to differentiate if we did not take into consideration and weigh carefully all the evidence presented by the various cases before forming our conclusions. Care in observation will in a great measure obviate the confusion that now exists in naming the two diseases. Those that have been in the habit of calling every sore-throat, with or without an eruption, scarlet fever, will be more careful, and be contented with the facts presented by each epidemic.

Case I.—May C., ten years old, came to my office about February 1st, complaining of sore-throat. I found the soft palate and uvala presenting a bright-red appearance, which extended to the posterior pharynx to a less degree. The tongue was covered with a whitish coat. There was an eruption on the face, hands, and trunk, presenting the appearance of a mild erythema, with a few well-defined points of a brighter red. The temperature and pulse were normal. I sprayed the girl's throat twice. She received no other treatment, and did not consider herself sick.

Cases II and III appeared at about the same time as Case I, but in another family. I likewise heard of several other cases appearing in different parts of the county simultaneously. My cases gave a history of chill, followed by mild fever, sore-throat, with an eruption that was decidedly red. Both were out in a few days.

Cases IV and V, one and three years old, respectively, had fever that ranged from 102.5° to 103° F.; the pulse was from 130 to 140. They had sore-throat, with induration and swelling of the post-auricular and post-cervical glands; the tonsils were considerably swollen. In one case, acute unilateral inflammation and in the other acute bilateral inflammation of the middle ear developed, terminating in suppuration. Neither presented an eruption.

Cases VI and VII occurred in the same family as Cases IV and V, in children five and ten years old, respectively. Both had sore-throat, with induration and swelling of the cervical glands, producing slight stiffness of the neck. Other symptoms were absent.

Case VIII.—Miss H., fifteen years old, was taken suddenly with a chill, followed by fever. The temperature rose to 103° F.; the pulse to 120. The throat was sore, especially the soft palate and the uvula. The tongue was covered with a whitish coat, which became brown and dry. Thirst was excessive. The post-auricular and post-cervical glands were slightly indurated and swollen, producing slight stiffness of the neck. The eruption first appeared upon the face, and rapidly spread to the body and extremities. It lasted for three days, when it began to fade, and was followed by desquamation in fine scales.

Case IX.—Mrs. H., the mother of Case VIII, forty years old, on the fourteenth day after the daughter became ill, was seized with a chill, followed by fever, the temperature rising to 108° F., the pulse to 120. The throat was sore. The post-auricular and post-cervical glands were indurated and swollen, with slight stiffness of the neck. Otitis media, with suppuration, developed. The eruption was slight, but general in distribution, and was followed by desquamation in fine scales. The patient gave a history of scarlet fever when a girl.

Case X.—My own baby, two years old, was seized with vomiting. The temperature and pulse remained normal, except when vomiting took place, when the pulse

would become accelerated. In the first twelve hours, the vomiting was almost uncontrollable, and at one time, after an hour's quiet sleep, she awoke and vomited blood three or four times. The throat was sore, but there was no eruption or glandular involvement. The cheeks would flush as though she had fever, but the temperature was always found to be normal. The hematemesis was controlled by one dose of liquor ferri subsulphatis; the vomiting by cocaine. Ice-cream was the only article of diet allowed for two days. A stomachic tonic of infusion of calumba was also given. Recovery was rapid and perfect. There is a light-brown discoloration left over the right mastoid process, about the size of a quarter. If there was any eruption at this point it escaped our notice.

CASE XI.—Mrs. L, fourteen days after exposure, without any warning was seized with a chill, followed by fever, the temperature reaching 103° F.; the pulse from 120 to 125. There was sore-throat, with induration and slight swelling of the cervical glands. The neck was slightly stiff. Vomiting was severe. The eruption was general and of a bright-red color. Desquamation took place in fine scales. The patient gave a history of scarlet fever when a girl.

CASES XII and XIII, two and four years old, respectively, were without warning seized with chill, followed by fever, the temperature ranging from 102.5° to 103° F.; the pulse from 120 to 130. There was sore-throat. A bright-red eruption appeared on the face and rapidly spread to the body and extremities. The eyes were red and watery. The voice was husky. The symptoms of coryza were marked, as was the case in varying degrees in all of my cases. The eruption lasted from three to four days, fading gradually. Desquamation took place in fine scales.

CASE XIV, the mother of Cases XII and XIII, fourteen days after the children became ill, was seized, without warning. with a chill, followed by fever, the temperature reaching 103° F.; the pulse 120. There was sore-throat. The eruption was general, and lasted three or four days, disappearing with very little desquamation.

CASE XV, the father of Cases XII and XIII, and the husband of Case XIV, became ill at the same time as did his wife. He had severe aching in the limbs and sore-throat. No other symptoms appeared. This aching of the limbs was a prominent symptom in all of the cases that were old enough to describe it.

CASE XVI.—Mrs. W., fifty years old, was seized with a chill, followed by elevation of temperature and acceleration of pulse, severe aching in the limbs, stiffness of the neck and soreness of throat, with induration and swelling of the post-cervical glands, which suppurated.

CASE XVII.—G. F., ten years old, became ill at about the same time and in about the same manner as Case I. The children were together every day, and the parents stated that both presented the same symptoms. No treatment was employed.

CASE XVIII.—M. F., a sister of Case of XVII, seven years old, became ill between two and three weeks after her sister. I did not see her, but her history, as obtained from her father, is that she was well at supper-time, but during the night felt chills and vomited once or twice. She appeared feverish. The eruption was profuse; it appeared on the face first, but in a short time the entire body and extremities had become involved. There was sore-throat. The treatment was mild.

CASE XIX.—A. F., a brother of Cases XVII and XVIII, five years old, twenty-one days after his sister became ill, presented symptoms similar to hers. The attack set in at night; on the following evening he had a light spasm. I found the boy with a temperature of 103.5° F., and pulse of from 130 to 140. There was twitching of the muscles, with mild delirium and frequent vomiting. On the following morning he was resting better; the temperature was 101.5°; the pulse from 115 to 120. The throat was sore; the tongue dry and brown; the nares almost occluded. The parents informed me that he had been troubled with catarrh of the nose for a month or so. The eruption had now become general, leaving no part exempt. The tonsils were swollen considerably; the post-auricular and post-cervical glands were indurated and swollen. The boy had played out of doors all or most of the day before he was taken ill. It was noticed that he sat upon the ground, which was wet. I saw him on the next morning, much improved; the temperature was 99° F.; the pulse 108; the swelling of the glands was apparently arrested. On the next morning he was still improving, and promised to make a speedy recovery; but in the night he became worse. I found him very restless; the temperature was 101° F.; the pulse 120; the glands and connective tissue of the neck were beginning to swell again, although the breathing was not much interfered with. After I had gone, the parents became alarmed and thought consultation advisable. When I returned at one o'clock to learn the hour of consultation, I found the boy with a temperature of 103° F. and the pulse from 130 to 140. In an hour I was sent for in haste, the messenger stating that the boy was choking. When I arrived I found him *in articulo mortis*. Cyanosis was marked and the breathing was very difficult. Diffused bronchial râles were heard over both lungs. I immediately performed tracheotomy, whereupon a quantity of mucus of a brownish color escaped through the opening. I inserted the tube and considerable more fluid ran out. The boy breathed full and easily for about one-half an hour, when death closed the scene. I believed that bronchitis had set in a few hours before, and was the immediate cause of death.

CASE XX.—B. F., a sister of Case XIX, two years old, became ill a day after her brother, both evidently having taken the disease from their sister, Case XVIII. The eruption and fever were the first signs. The eruption was marked, presenting a bright-red appearance. The throat was sore; the post-cervical glands were indurated and swollen; these broke down after being poulticed. The tongue was dry and brown. Sixteen days after the onset of the attack, the parents gave the girl two doses of quinine, the amount of which was probably three or four grains in all. This served to cause an attack of hives. Otherwise she has done well.

The point to which I wish to call attention is the epidemic character of the affection. It seemed that almost every one was under its influence more or less. Its contagious character was manifested in its transmission from one member of a family to the others, while in some cases it was carried from one family to another by a susceptible individual. The cases were also mostly mild,

only one proving fatal, and that evidently from a complication. Two of the adults had previously had scarlet fever. Nearly all presented more or less induration and swelling of the post-auricular and post-cervical glands. None of the usual complications and sequelæ of scarlet fever were observed. The strawberry tongue was not encountered. My plan of treatment has been entirely symptomatic. I gave sodium salicylate and antifebrin in equal parts to control the fever, the dose being regulated to suit the individual case. Due attention was given to the secretions. An antiseptic throat-wash was used five or six times or oftener a day, according to the urgency of the case. Cocaine and bismuth subnitrate were given for vomiting when indicated. As a tonic I gave elixir of iron, quinine, and strychnine. For nourishment I relied on milk, soft-boiled eggs, ice-cream and meat-broth.

A CASE OF ECLAMPSIA; FOLLOWED BY FACIAL ERYSIPELAS; RECOVERY.

BY ALBERT PICK, M.D,
OF MANCHESTER, N. H.

MRS. P., a German, thirty-two years old, was a weak, delicately built deutipara. She had had typhoid fever when ten years old, which was followed by almost complete alopecia. Otherwise she had always been healthy. Her first child was born eight years ago at full term, after a tedious but normal labor. A few weeks previously to the present confinement, at full term, she suffered from vertigo and headache.

I was called to see the woman on March 22d at 2 P.M. Just as I entered the sick-room she had a severe convulsion, lasting for about two minutes. Another followed in twenty minutes. There was stertorous breathing and the pupils were perfectly reactionless. Her attendants stated that she had felt some labor pains on the previous night. She had been unconscious since 6 A.M.; the convulsions beginning at that time. The physician who had attended her in her former confinement was sent for, and, without making a vaginal or other examination assured the friends that the condition was not serious, and that the patient would soon be "all right." At 9 A.M., when he came again, the patient had a severe convulsion.

At 2 P.M. I was sent for; the patient now having convulsions every half-hour. I immediately made a vaginal examination and found the os externum very rigid, with no signs of labor. As the patient was unconscious and could not swallow, I administered one dram each of chloral and sodium bromide by the rectum, and then put her into a hot pack. While I was carrying out the procedures the patient had two convulsions. After I had put the patient into the hot pack I went for my colleague, Dr. J. L. Robinson, to assist me in the induction of labor and in the further management of the case. I left some pearls of amyl nitrite (each containing four minims), with instructions that one should be crushed in a handkerchief, and the directions that the patient be made to inhale the vapor in case the necessity arose.

On my return with Dr. Robinson, I learned that the patient had been breathing more quietly, had perspired freely, and that she had not had any more convulsions.

We found, on vaginal examination, some dilatation of the os, which was yet rigid, as was also the perineum Methodical dilatation was at once instituted, and, after the cervix was sufficiently dilated, the membranes were ruptured. Labor-pains now appeared more frequently and were of better quality and more lasting.

L. O. A. was diagnosticated. At 6 P.M. the head was born; expulsion of the trunk quickly followed. The cord was wound several times around the neck of the child. The latter showed signs of impeded circulation, and after a few short and feeble efforts of respiration it seemed to give up. Considerable time was spent in efforts to restore life, which finally were crowned by success.

The placenta came away at the expiration of half an hour. After the patient had been cleaned and dressed, she fell into a profound sleep, consciousness not being restored until the next morning. The chloral and sodium bromide were continued during the night and following day—in smaller doses, of course. The woman complained of pain in the muscles of the face for several days; especially painful were the muscles attached to the lower jaw.

Otherwise convalescence was uneventful until the fourth day post-partum, when, coincidently with a rise in temperature, facial erysipelas developed. The face was much reddened, considerably swollen, and very painful. The temperature rose to 104° F. The patient was given gr. iij of quinine and gr. $\frac{1}{10}$ of extract of belladonna four times daily; locally, an oxide of zinc and bismuth subnitrate salve was used. As the bowels were somewhat sluggish, fluid extract of cascara sagrada was added to the treatment. The diet was liquid, but nutritious. The patient improved rapidly, and a week later was out of bed and made an uninterrupted and uneventful recovery.

Rapid emptying of the uterus was the main measure relied upon in the management of this case of eclampsia, and the result was satisfactory and speedy to both patient and accoucheur.

MEDICAL PROGRESS.

Death after the Intra-uterine Injection of Ferric Chloride. —PLETZER (*Centralbl. für Gynäkologie*, 1892, No. 18, p. 337) reports the case of a woman, thirty-two years old, that presented herself with retroversion of the uterus and chronic endometritis. There was a history of syphilis, of repeated miscarriage, and of cerebral hemiplegia. The cavity of the uterus was curetted and tincture of iodine was applied. A Hodge pessary was employed to keep the organ in position. A small myoma was found upon the posterior uterine wall. After four days of rest in bed, the uterus was irrigated with a 2 per cent. solution of carbolic acid, and tincture of iodine was applied. The next menstrual period occurred at the expected time; the flow was full and lasted a week. Subsequently the treatment was resumed; the injections were made at intervals of two days. Considerable hemorrhage ensuing on one occasion, a half-dram of the official solution of ferric chloride was, by means of a syringe with lateral fenestra, slowly injected into the disinfected uterus and permitted to flow out, the uterus afterward being irrigated with a 2 per cent. solution of carbolic

acid. The patient was put to bed. She complained of intense abdominal pain; the skin became livid, the pulse small and frequent, the breathing stertorous. Despite the energetic application of remedial measures, the woman died two and a quarter hours after the injection had been given. At the autopsy an old hemorrhagic area was found in the left optic thalamus. The right heart contained numerous thrombi situated among the trabeculæ. The pulmonary veins and their branches contained a few loose thrombi. From the right internal iliac vein, at the point of bifurcation of the common iliac, protruded a thrombus more than an inch long. The posterior surface of the interior of the uterus presented a longitudinal defect about a half-inch long, resembling a tear of the mucous and muscular coats, perhaps a fifth of an inch deep. At the bottom of this defect were visible numerous small veins filled with dry, black, firm clots. One of these veins could be traced as a thick cord through the pelvic connective tissue to the common iliac vein. The blood throughout the body was fluid.

Cranial Surgery. — At a meeting of the Philadelphia County Medical Society MORRISON reported three interesting operations in cranial surgery. One case was that of a forceps-delivered boy, two years and seven months old, with defective mental development, in which linear craniotomy was performed. Improvement soon followed upon operation, and was persistent thirteen months later. The second case was one of epilepsy in a boy, eight years old, in which the convulsive movements were most decided upon the right side of the body. The skull was trephined above and in front of the point of intersection of the temporal ridge and the coronal suture on the left, but nothing abnormal was found. Slight temporary improvement followed upon the operation, but the paroxysms soon recurred with their previous frequency and severity. In the third case, a subdural abscess formed as the result of a blow upon the head, with fracture of the internal plate of the bone. A wound of the scalp and bone had been inflicted in front of and parallel with the left Rolandic line. Consciousness had not been lost. There was some nausea and vomiting. Four days after the accident, pain in the left temple set in. On the eighth day, loss of power was noted in the right arm and leg, which on the ninth day had progressed to complete paralysis, including likewise the right side of the face. The skull was trephined in front of the original wound. The internal plate of bone was found separated from the external plate for half an inch on each side of the opening. An extra-dural clot was present. The removal of a fragment of bone that had penetrated the dura permitted the escape of an ounce of pus. The dural opening was enlarged and the abscess-cavity irrigated. Drainage was provided for. The patient made a satisfactory and speedy recovery.

Anthrax.—From a careful study WISSOKOWICZ (*Fortschritte der Med.*, 1892, Nos. 11 and 12) has found that cases of cutaneous anthrax occur in man in which, in the course of the general disease, the anthrax-bacilli disappear from the primary focus. In all cases at not too early a stage the death of the bacilli may be observed at the periphery of the diseased area, without the participation of leukocytes. The dissemination of the anthrax-bacilli from the primary subcutaneous focus takes place in the rabbit (and probably likewise in man) exclusively by the lymph-stream. The bacilli that find their way into the blood at the conclusion of the illness are not excreted by the liver or the spleen, in contrast with what occurs when bacilli are experimentally injected into the blood of a healthy animal. The elimination of virulent anthrax-bacilli also takes place through the capillary endothelium of various organs, without the participation of the leukocytes. Cells of organs unpoisoned by anthrax-toxines possess the capability of taking up living anthrax-bacilli; poisoned cells lose this property. The elimination of the bacteria from the blood in the organs and their taking up by the fixed cells of the connective tissue have but a secondary significance in the battle of the organism with the virus. The most important rôle belongs to the antiseptic (bactericidal) property of the tissue-fluids (the natural cell-products), and next, to the blood. On preserving, in the cold, the organs of animals dead of anthrax the number of bacilli rapidly diminishes in the course of twenty-four hours.

The Surgery of the Gall-bladder.—CZERNY (*Deutsche medizin. Wochenschr.*, 1892, No. 23, p. 516) thus summarizes his views on the surgery of the gall-bladder: Gall-stones require operation when they occasion repeated or persistent distress. Empyema of the gall-bladder demands operation; hydrops, if it occasions distress. The typical operation for stone in the bladder consists in incision, evacuation, and suture, the abdominal wound being drained for a short time. If the cystic duct be not patulous, if the gall-bladder is inflamed, if the contents have undergone marked change, a temporary biliary fistula should be established. The gall-bladder should be extirpated only in case of intense inflammatory conditions, or of carcinoma. If the common duct be occluded operation is absolutely indicated as long as the strength of the patient will allow. If the obstruction (stone or flexion) be not remediable, the best procedure is to establish a communication between the gall-bladder and the duodenum. The best mode of procedure is to make a hook-shaped incision, the vertical arm of which lies in the linea alba and the horizontal arm extends toward the right, just below the level of the umbilicus. Operation for gall-stones is attended with less danger than operation for vesical calculi.

Immunity to Cholera.—VINCENZI (*Deutsche medicin. Wochenschr.*, 1892, No. 18, p. 394) has found that the subcutaneous intra-pleural or intra-peritoneal injection of a drop of a bouillon-culture of cholera-bacilli causes in guinea-pigs extensive edema, followed by death in from twenty to thirty hours. The blood and the intestine of such animals contain living cholera-germs. Infection takes place by the intestinal tract only if the bowel be irritated, mechanically or chemically; alkalization of the stomach is unnecessary. The blood-serum of normal guinea-pigs is incapable of destroying the virulent cholera-bacilli when present. Animals treated with a filtrate of a bouillon-culture of cholera-bacilli are protected against infection. In immune animals the subcutaneous injection is followed by marked phagocytosis. The blood-serum of immune guinea-pigs transmitted to other animals confers immunity.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, JULY 30, 1892.

SHALL THERE BE A FOUR YEARS' COURSE?

WITH the recent action of the Association of American Medical Colleges the compulsory three years' course may be regarded as an accomplished fact. The advocates of advanced education are, however, not satisfied with this. The voluntary four years' course is an old thing; the compulsory four years' course, recently adopted by Harvard, by the Woman's Medical College of Pennsylvania, and by the University of Pennsylvania, is not now first heard of; but the agitation to make all of the schools of high grade four years' schools, and thus to draw as sharp a line between them and the "three-termers" as formerly existed between the "three-termers" and all but the exceptional "two-termers," is daily becoming more active.

At first sight, the movement seems worthy of enthusiastic encouragement. On further reflection, however, the thought occurs that perhaps the result aimed at can be more effectively accomplished by other means. If by three years' attendance upon college, under certain conditions, one can be as well and as thoroughly equipped for the duties of the physician as he could be by four years' attendance under present conditions, all will agree that the enforced loss of another year in pupilage may well be spared.

The present college-term occupies six months. Why should medical students have six months vacation, while other students are mentally and physically satisfied with three months vacation? Three terms of eight months each will surely give the student as much instruction as he can get in four terms of six months each, and will probably give him more instruction by enabling subjects to be thoroughly treated that are now unavoidably slurred over.

There is no good reason why the college-term should not be lengthened to eight months, or even to nine months, and there are many reasons why it should be so lengthened.

Then, again, much time is now wasted in all our colleges, even in those that require the highest standard of entrance-qualification, in teaching subjects with which the student should be thoroughly familiar before beginning his medical education; and many subjects that ought to be taught are omitted because even after three or four years' attendance upon lectures, the student lacks the necessary training to appreciate these subjects.

Chemistry and physics offer the most striking examples. Neither physiology, pathology nor therapeutics can be thoroughly understood by one who has but a superficial acquaintance with chemistry and physics; yet in no medical college in the United States is there even a pretence of a proper teaching of these fundamental sciences, or a proper entrance-qualification therein demanded. The year or two years spent in teaching elementary chemistry is that much time wasted, when viewed from the standpoint of modern medical science. Almost all that is now taught should be demanded as part of the qualification preliminary to entrance; and the medical student should be instructed in those now recondite mysteries of animal and vegetable chemistry, the chemistry of life, disease and death, through and by which the future triumphs of medical art and science are to be won.

Why is it that the brilliant researches of the day into the causation of disease, the processes of infection, recovery and immunity, the ultimate action of drugs in the animal economy, are so much Greek to the average American physician? Simply because he has not been taught the chemical A B C of the language in which these researches are conducted.

With physics the case is even worse. Men may be admitted to medical schools who scarcely

understand what is meant by the center of gravity, who know nothing of the laws of light, and who have but the vaguest idea of electricity as something that gives shocks and is somehow concerned in telegraphy and other modern wonders. Of what earthly use is it to talk to such men of blood-pressure, of refraction, of molecular vibration? They may learn how to manipulate trial-lenses and test-types, how to place sponges on nerve and muscle-points, and even to avoid the use of digitalis in patients with marked atheroma; but it is all in a bungling apprentice fashion; it is mere simian imitation; there is no intelligent understanding of anything beyond the simplest mechanical routine.

In every college there should be a chair of Medical Physics co-equal with the chair of Medical Chemistry, and the entrance-qualification in chemistry and physics should be such as to leave the chairs free to teach the advanced technical chemistry and technical physics necessary to a complete medical education. This, in turn, would necessitate a knowledge of mathematics possessed by few of the present race of medical students.

In languages, a fair knowledge of elementary Latin and Greek should be required—but likewise some acquaintance with French and German; for while it is true that a knowledge of results can be obtained by the student from his teachers and from English medical literature, yet the reading of certain great monographs in the original is in itself an introduction to methods of investigation and habits of thought of no mean importance in moulding the career of the physician.

Thus, if a fourth year is to be added to the term of medical study in America, it can best be added as a preparatory course; offering to those without adequate preliminary training in the fundamental natural sciences and in the necessary languages the opportunity to equip themselves. It should not be required of those already thoroughly equipped. Such a preparatory course could also well include an introduction to biology and technical training in the use of the microscope; and indeed Harvard will, under the new rules, admit to advanced standing graduates of scientific or classical schools in which histology, anatomy, physiology and chemistry are taught. An adequate biologic course should likewise be added to the first and second years' studies; and in time this should be gradually advanced and enlarged and a preliminary biologic qualification be required.

If, then, the qualification for matriculation at colleges of medicine be made adequate; if the terms be lengthened to eight or nine months each, and if the third year be largely devoted to clinical work, we see no necessity for a compulsory four years' course for the medical practitioner. Those who desire to be investigators and teachers, or to devote themselves to special lines of work, should have the opportunity of electing certain additional laboratory or clinical courses for a fourth, a fifth, or a sixth year of study. Some fitting recognition might be devised as reward for such additional devotion to science.

The Medical Department of Grant University at Chattanooga offers two diplomas—the ordinary diploma for the present two years' course, and a different diploma for three years of study. So too, the Medico-Chirurgical College of Philadelphia offers the degree of M.D. *cum laude* for four years' work. A better, though we fear impracticable, plan would be the granting of the degree of Bachelor of Medicine (with the right to practise, subject to State laws) after three terms of eight months each, and the doctorate in recognition of one or more terms of additional work at any subsequent time.

THE DIFFERENTIAL DIAGNOSIS OF RÖTHELN, MEASLES, AND SCARLATINA.

IT is only within the last quarter of a century that Rötheln has been fully recognized as a distinct disease. Previously it had been regarded by some as an irregular form of scarlet fever; by others as an irregular form of measles, and by a third group of physicians as a hybrid of these two diseases. There were yet others who looked upon it not as an exanthem at all, but as a mere symptomatic rash, like urticaria or erythema; hence it came to be occasionally described as an epidemic roseola.

The early observations of STEINER, THOMAS, and others, and the more recent studies of such close observers as CHEADLE, EDWARDS, and GRIFFITH not only leave no room to doubt that Rötheln is a specific, infectious, and highly contagious disease, but they have also determined its constitutional and cutaneous characters with exactness, and its entire independence as a substantive affection. The descriptions of these observers, however, and those of other writers upon the subject by no means tally, and the practitioner who, for the first time finding himself in the midst of an epidemic of an eruptive disease

that, from his general reading, he suspects to be Rötheln, turns to his books and looks for the accounts of this disease one after another, will probably end in confusion worse confounded.

The cause of these wide differences is fourfold. First: Rötheln is a comparatively new or newly-known disease, and the observer who has not yet beheld it in all its phases places upon record views necessarily incomplete. Second: It is a disease of wide divergence from type, not alone as regards individual cases, but even as regards whole and extensive outbreaks. Therefore, one who has seen much of it may readily mislead himself into the belief that his description covers the entire ground. Third: It is a malady intensified to a remarkable degree in public institutions, in which it occurs with a severity not seen in private practice. The asylum physician, therefore, describes a disease unknown to the most experienced outside practitioner. Finally: The traditions still have a measure of influence, and here and there may be detected more stress upon its likeness to measles or scarlatina than upon its unlikeness to them, or upon the trenchant lines that separate all three.

It is thus no matter of wonder that the differential diagnosis between Rötheln and measles, on the one hand, and scarlatina, on the other, still vexes the minds of practitioners. If all three diseases were equally unimportant, and the diagnosis were without bearing upon immediate action for the prevention of outbreaks of grave disease in households, schools, or communities, the physician might, in a given case, be permitted to temporize. But it is not so. The public demands and the physician feels himself impelled to an early decision. The period of isolation for the settling of doubts must be short. *Omne ignotum terribile.* The case in question, mild as it is, may be a case of scarlet fever or measles—a choice of evils in a school.

In contrast with measles and scarlatina Rötheln presents as a rule slight and transient fever or other constitutional disturbances; often so trifling as to attract little attention, often absent altogether. The eruption appears early; it is in many cases the earliest manifestation. It is irregular in character and distribution. It commonly appears first about the head and face, and sometimes resembles that of measles; but the macules are of a brighter pink and do not tend to the crescentic arrangement; less often it resembles that of scarlet fever; but it is paler. It appears and disappears irregularly over the surface, so that a fresh patch may show itself just as a patch elsewhere is fading. Catarrhal manifestations are slight and as a rule restricted to the upper air-passages. The lymphatic glands of the neck are more or less swollen, the posterior rather than the anterior chains being infiltrated; and this is an early symptom. At the end of four days, sometimes as late as the fifth or sixth day, the rash vanishes without desquamation, save where it has been unusually intense.

Throat-symptoms, if present at all, are trifling and unlike those of scarlatina; catarrhal bronchitis does not occur; the initial fever, when present, subsides slowly rather than abruptly, and is insignificant; the temperature does not often reach 101° F.; moreover, the pyrexia is transient, differing in all these respects from that of measles and that of scarlatina. Chill, convulsions, and vomiting do not mark the invasion. If the eruption suggests measles of a mild type, the constitutional symptoms declare for Rötheln; if the rash resembles that of an atypical scarlet fever, the absence of the characteristic general disturbances of the latter points the way to a diagnosis.

Cases of Rötheln occur, as in the other eruptive diseases, in which for a time the diagnosis is impossible, but, in proportion as we attach importance to the broad distinctive traits of the disease and ignore minor symptoms, the number of these cases rapidly diminishes.

THE RETIREMENT OF PROFESSOR DA COSTA FROM JEFFERSON MEDICAL COLLEGE.

WE are authoritatively informed that PROFESSOR DA COSTA will not again take part in the clinical lectures at Jefferson Medical College. This announcement can occasion only profound regret among the friends and alumni of the college, with whom the name of DA COSTA stands for the embodiment of what is best and noblest in medicine and as representative of the ideal in teaching. DR. DA COSTA'S resignation from the Chair of the Practice of Medicine is yet fresh in memory. By the action of the Board of Trustees of the College he was made Emeritus Professor in the department that he had for so many years conducted with such signal ability and distinction, and upon the invitation of the Faculty he delivered his usual course of clinical lectures last winter. DR. DA COSTA has now withdrawn from all teaching connection with Jefferson College. He will, however, continue as Visiting

Physician to the Pennsylvania Hospital, and in connection therewith will deliver the usual course of clinical lectures.

REVIEWS.

TEXT-BOOK OF THE ERUPTIVE AND CONTINUED FEVERS. By JOHN WILLIAM MOORE, B.A., M.D., M.Ch., University Dublin; Fellow and Registrar of the Royal College of Physicians of Ireland; Physician to the Meath Hospital, Dublin, etc. 8vo, pp. xxv, 535. New York: William Wood & Co., 1892.

IT is a great pity that a book so full of information, so philosophic in its conception, so lucid in its expression as is the one before us, should be so badly printed as to destroy the pleasure that would otherwise be experienced in reading it.

It begins with an Introduction, the successive chapters of which treat of the intimate nature of fever, the intimate nature of contagion, the micro-parasitic diseases, and the general principles of treatment of the eruptive and continued fevers, the latter topic being subdivided into two heads—preventive treatment and curative treatment.

Part II. deals with the exanthemata, under which head the author includes erysipelas. Part III. deals with the continued fevers—febricula, typhus, typhoid and relapsing fevers; while the concluding chapter reviews recent investigations into the subjects of infection and immunity. There is an excellent index.

The author treats fully and intelligently of the pathology, the symptomatology in detail, the diagnosis, prognosis, and treatment of the various diseases studied. He has drawn freely upon literature, classic and ephemeral, but everything has been subjected to the touchstone of his own rich experience and ripe judgment.

The book is a welcome addition to literature, and will be extremely useful alike to the practitioner of experience and the younger man seeking safe guidance and wise counsel.

SPECTACLES AND EYE-GLASSES: THEIR FORMS, MOUNTING, AND PROPER ADJUSTMENT. By R. J. PHILLIPS, M.D. With forty-seven illustrations. Philadelphia: P. Blakiston, Son & Co., 1892.

IN writing this most excellent little treatise, Dr. Phillips has performed a genuine service alike to the profession, the trade of the optician, and the public. So much was the work needed, and so well is it done, that even a slight word of criticism seems ungrateful. Even those who know the great medical importance of a proper correction of errors of refraction have generally or often been sadly neglectful of a matter that is of exactly equal importance—the proper manufacture and fitting of the spectacles. Both physician and, strange to say, the optician, have been unaccountably indifferent in the matter. It is to be hoped that this little volume may help toward a recognition of the mistake, and may possibly lead to larger and completer, more detailed, handbooks upon the subject. In the reviewer's opinion, Dr. Phillips should have been far less lenient as regards eye-glasses, inferior therapeutically as they generally are to spectacles. And he should not have failed to condemn emphatically and explicitly the flimsy, good-for-nothing, limp, and stringy temple wires and bridges commonly sold by the commercialized optician.

TRAITEMENT DES PLEURÉSIES PURULENTES. Par G. M. DEBOVE et M. COURTOIS-SUFFIT. Small 8vo, pp. 231. Paris: J. Rueff et Cie, 1892.

THIS is the second of a series of neatly bound and inexpensive books written by standard authors and issued under the direction of Charcot and Debove. The work starts out with the proposition that purulent pleurisy is not a single morbid entity, but that the process differs and the therapeutic procedure must be selected in accordance with the differing pyogenic organisms present. The subject is presented in three parts. In the first part the evolution of the current methods of treatment is traced. The second part considers these methods in detail, together with an analysis of their *rationale*, the indications for their individual selection, the dangers of operation, and the means of obviating them. In the third part of the work, the different varieties of purulent pleurisy, with their distinguishing clinical characteristics, and the respective indications for treatment are presented. The book can be cordially commended and may be read with much profit.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, held at New London, Conn., July 19th, 1892.

THE Society was called to order by the President, DR. GORHAM BACON, of New York.

DR. OREN D. POMEROY, of New York, read a paper entitled "Cases of Mastoid Disease Exhibiting Somewhat Extensive Carious Processes." He reported six cases in which no effort was made to remove all of the dead bone, but whatever was loose or readily detachable was taken away. Adequate antiseptic drainage was carefully looked after, and the vital energies were kept up by stimulants, tonics, food, and proper nursing.

It seems unaccountable that only one of these cases resulted fatally, when it is known that any considerable quantity of dead bone in the vicinity of the brain may induce fatal cerebral disease. It does not seem proper to attempt the removal of dead bone if the meninges are in danger of being encroached upon.

Numerous cases are on record in which a considerable portion of the bone has separated, leaving uncovered meninges, without fatal consequences. Moreover, when all the dead bone is removed, reparative action does not commence until a new barrier of dead bone has been established.

DR. B. ALEXANDER RANDALL, of Philadelphia, presented "Preliminary Notes on Craniometric Studies in Relation to Aural Anatomy." Only 122 skulls, 73 broad-headed, 33 long-headed, and 16 medium in index were used in the tabulation, and the only clear showing was that maximum or minimum dimensions might be found on either side and in any form of skull. The

greater danger of the right side and of the brachycephalic skull receives slight confirmation, the cerebral fossa being actually more often lower on the left; but no deductions should be attempted from so small a series of cases, and any indications are probably worthless that are derived from less than one thousand skull-measurements.

DR. CHARLES J. KIPP, of Newark, N. J., reported "A Case of Purulent Inflammation of the Middle Ear, with Double Optic Neuritis and Other Symptoms of Intracranial Lesion, but without Tenderness of the Mastoid Process, in which the Opening of the Mastoid Cells was Followed by Rapid Subsidence of the Optic Neuritis and Cure of the Disease." Particular attention was called to the absence of tenderness over the mastoid process even on percussion, and to the desirability of repeated opthalmoscopic examination in prolonged middle-ear disease.

DR. C. J. BLAKE, of Boston, read "A Report of Mastoid Cases." Of twenty-five cases of mastoid congestion and inflammation seen in the first six months of this year, three were treated by the continuous cold coil with excellent effect; twenty-two were operated on at various stages and with various complications. Two cases died; one, complicated with pneumonia, on the ninth day; and the other, with meningitis from extension of the suppurative process from the middle ear through the tegmen tympani, on the tenth day.

DR. H. KNAPP, of New York, reported "A Case of Chronic Purulent Otitis Media; Old Pulmonary Tuberculosis; Opening of Mastoid; Death from Acute Basilar Meningitis; Autopsy." The patient was a man of thirty-five, who complained of headache. The temperature rose slightly, but there was no tenderness over the mastoid process. Subsequently, drowsiness developed, with nervous movements of the hands. For three years there had been a discharge from the right ear, which ceased for a week. The temperature reached 102.2°. There was headache, stupor, incoherence and difficulty of speech, and delirium. The pupils and fundus were normal. There was no pain on percussion of the skull. The mastoid process was opened and found sclerotic throughout. The superficial portion of the bone presented some evidence of disease, but the deeper parts appeared healthy. The patient sank and died a few days after the operation. The autopsy disclosed the existence of basilar meningitis and the lungs presented evidences of pulmonary tuberculosis.

DR. J. B. EMERSON, of New York, reported "A Case of Pyemia Following Acute Suppurative Otitis: Recovery." The patient was a woman, twenty-four years old, who, following an attack of influenza, had pain in the left ear, followed by a purulent discharge. While under observation, signs of septic pneumonia appeared. Successive abscesses developed over the right sterno-clavicular articulation, over and above the sternum on the left side of the neck. The patient, nevertheless, slowly and steadily improved, the treatment extending over a period of four months.

DR. T. Y. SUTPHEN, of Newark, N. J., read a paper entitled "Mastoid Operation in a Case of Middle-ear Disease, with Septicemic Symptoms and Cerebral Complications." The case was that of a girl, sixteen years old, with chronic otitis media of the left ear for several years. For a few days there had been intense pain and a temperature of 105°. There was no sign of mastoid trouble other than the pain. General septicemic symptoms appeared. A hard swelling was discovered beneath the sterno-cleido-mastoid muscle. The mastoid process was opened. Only a drop or two drops of purulent fluid were found. The condition of the patient continued unfavorable until pus began to flow freely from the mastoid wound. The temperature then fell to 99°, and the patient made a rapid recovery.

DR. GORHAM BACON, of New York, reported "A Case of Mastoid Disease Following an Operation for the Removal of Adenoid Vegetations." The patient was a woman, thirty years old, who had had adenoid vegetations removed from the naso-pharynx during an attack of subacute pharyngitis. Two days later she had severe pain in the right ear, followed by a muco-purulent discharge. Symptoms of mastoid disease being present, she was immediately put to bed, a Leiter coil applied, and the ear douched frequently with a warm boric acid solution. The mastoid symptoms soon disappeared.

Subsequently a periosteal abscess on the right side was opened and about a dram of pus escaped. The patient made a good recovery, and at no time did the temperature rise above 100° F.

DR. SAMUEL THEOBALD, of Baltimore, read a paper "On the Value of Weak Solutions of Bichloride of Mercury in the Treatment of Otitis Media Suppurativa." He reported good results from the employment of weak solutions (usually 1 to 8000) of mercuric chloride, with which the ear is simply syringed. In otorrhea it was usually not necessary to repeat the syringing more than once in twenty-four hours.

DR. H. KNAPP, of New York, exhibited a specimen showing perforation on the medial side of the mastoid, removed from a patient dying from cranial abscess.

DR. D. B. ST. JOHN ROOSA, of New York, read a paper entitled "Wound of the Lateral Sinus in the Course of Mastoid Operation, Followed by Septicemia, with Recovery." The patient was a young woman, twenty-three years old, who for years had had recurrent attacks of suppuration of the left ear. It was thought that the mastoid process was carious, and it was decided to open it by means of the drill. A large cavity was found, from which issued a gush of venous blood, which could not be checked by ordinary means. It was believed that the lateral sinus had been perforated. The wound was plugged with iodoform-gauze. Four days later, when the wound was dressed, there was no trouble from bleeding. Symptoms of septicemia then set in, but after two months of expectant treatment the patient completely recovered.

DR. F. L. JACK, of Boston, read a paper entitled "Remarkable Improvement in Hearing by Removal of the Stapes." He reported the case of a girl, twelve years old, with chronic suppurative otitis, in which portions of the membrani tympani, the malleus, the incus, and the stapes were removed. There was little hearing in the affected ear. On the morning following the operation the hearing was much better.

DR. C. J. BLAKE, of Boston, read a paper entitled "Middle-Ear Operations." He stated that in chronic non-suppurative disease of the middle ear, when surgical interference is determined upon on account of

obstruction to the sound-transmission through the ossicular chain, the removal of the incus or malleus may be considered as merely incidental, since the stapes is the important element. Various procedures for the immobilization of the stapes have been proposed and practised, but the removal of the stapes has until recently been left out of serious consideration. The justification of this procedure is to be premised from the fact that the stapes is especially liable to be tied down by the reduplications found in about 80 per cent. of normal ears.

DR. B. ALEXANDER RANDALL, of Philadelphia, read a paper entitled "Excision of Membrane and Malleus for Catarrhal Deafness, Followed by Suppuration, Mastoid Empyema, and Burrowing Abscess of the Neck." The case was one in which ordinary methods proved unsuccessful. The incus was pushed up and not extracted. Five days after the operation, marked febrile symptoms appeared and a profuse muco-purulent discharge set in. In the course of four weeks, it was clear that a mastoid empyema was breaking into the digastric fossa. An incision was made over the mastoid, the pus evacuated, the bone sinus scraped, and the outer surface of the mastoid trephined, opening the antrum freely. On irrigation the fluid found its way into the pharynx by a lower opening; the temperature fluctuated greatly during the following fortnight, with oculo-motor paresis, diplopia, and some mental aberration, suggestive of intra-cranial abscess. Recovery ultimately ensued, but there was no improvement of hearing.

DR. D. B. ST. JOHN ROOSA, of New York, reported "A Case of Exostosis of the External Auditory Meatus." The patient was a woman forty-six years old, who for twenty-one years had impairment of hearing and tinnitus in the right ear, and at times pain in both ears. The external auditory canal was almost completely closed by a bony growth at the junction of the osseous and cartilaginous portions. The woman could hear a watch only on contact. The mass sprang from the posterior wall, and left a small space between it and the anterior wall. On operation it proved to be a very thin plate of bone, and was removed by the chisel without difficulty. The patient did well, and the hearing distance for the watch became 12/XL.

DR. C. J. BLAKE, of Boston, stated that in two different families he has seen multiple exostoses occurring in three generations, in grandfather, father, and son.

DR. R. A. REEVE, of Toronto, reported a case of exostosis of the meatus, in which the growth had become so large as to press upon the tissues of the opposite wall of the canal, causing intense suffering and demanding operation.

DR. E. E. HOLT, of Portland, Me., exhibited an ear bitten off by a horse, and made a brief report of the case.

DR. C. J. BLAKE, of Boston, exhibited the plans for the new Aural Building of the Massachusetts Charitable Eye and Ear Infirmary.

The following officers were elected: *President*, Dr. Gorham Bacon, New York; *Vice-President*, Dr. Huntington Richards, Des Moines; *Secretary and Treasurer*, Dr. J. J. B. Vermyne, New Bedford, Mass.; *Member of Executive Committee of Congress of American Physicans and Surgeons*, Dr. William H. Carmalt, New Haven; alternate, Dr. F. B. Loring, Washington.

The following were elected to membership: Dr. J. Elliott Colburn, of Chicago, Ill.; Dr. Robert Tilley, of Chicago, Ill.; Dr. B. F. Milliken, of Cleveland, O.

NEWS ITEMS.

University of Pennsylvania.—The *compulsory four years' course* goes into operation with the session beginning October 2, 1893. It is announced that as a desire has been expressed by some students to avail themselves of such a course at once, it has been decided to offer the opportunity of a full four years' graded course to those who desire it with the opening of the next session beginning October 2, 1892.

Dr. Tyson has resigned the position of Dean, and Dr. John Marshall has been chosen to succeed him.

The National Popular Review is the name of a new "illustrated journal of preventive medicine and applied sociology for the profession and the people," published at San Diego, and under the editorial charge of Dr. P. C. Remondino. The first number bears date of July, and contains a number of interesting articles, excerpts, and reviews. The subject-matter is of such a character as will likely attract professional and popular interest.

Yale University.—At the recent graduation exercises of the Medical Department of Yale University the degree of Doctor of Medicine was conferred upon twenty-two graduates. Dr. George M. Sternberg, U. S. A., read the Annual Address in Medicine, on "The Etiology of the Infectious Diseases, with the Explanation of Acquired Immunity from these Diseases."

University of Vienna.—Otto Bergmeister has been elected Professor Extraordinary of Ophthalmology; Josef Englisch, Professor Extraordinary of Surgery; Ferdinand Hochstetter, Professor Extraordinary of Anatomy; Alexander Kolisko and Richard Paltauf, Professors Extraordinary of Pathologic Anatomy.

Rush Medical College.—Dr. Charles Warrington Earle has been called to the chair of Obstetrics and Diseases of Children in Rush Medical College, recently made vacant by the death of the late Professor Knox. Dr. A. C. Cotton has been elected Clinical Professor of Diseases of Children.

The American Therapist is the name of a new monthly, the initial number of which is dated July. Dr. John Aulde is the editor.

Pravaz, the inventor of the hypodermatic syringe, died recently at Lyons.

BOOKS AND PAMPHLETS RECEIVED.

Elements of Materia Medica and Therapeutics, including the Whole of the Remedies of the British Pharmacopeia of 1885 and its Appendix of 1890. By C. E. Armand Semple, B.A., M.B. Cantab., M.R.C.P. Lond. With 440 Illustrations. London: Longmans, Green & Co., 1892.

The Pathology and Rational Treatment of the Uric-acid Condition. By James Wood, M.D. Reprint, 1892.

The Pulmonary Complications of Influenza. By J. M. Da Costa, M.D., LL.D. Reprint, 1892.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXI. SATURDAY, AUGUST 6, 1892. NO. 6.

ORIGINAL ARTICLES.

INFLAMMATION IN THE RIGHT ILIAC FOSSA, ASSOCIATED WITH LESION OF THE CECUM, THE VERMIFORM APPENDIX AND ADJACENT TISSUES.[1]

BY JOHN B. DEAVER, M.D.,

PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC; ASSISTANT PROFESSOR OF APPLIED ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA.

IT was with no little hesitancy that I selected for the subject of my remarks "Inflammation in the Right Iliac Fossa, Associated with Lesion of the Cecum, the Vermiform Appendix and Adjacent Tissues," as I was conscious that the part of the subject coming especially under the head of appendicitis is one upon which much has been written. My apology, therefore, is that I hope to present it in a somewhat different manner than it is usually dealt with, and, to insist upon the importance of the surgeon being called in counsel earlier than has been the custom. So often have I been impressed with the responsibility of the position of the physician who is called to treat cases of this character and does not seek the advice of the surgeon until the eleventh hour, when, perchance the patient has developed a diffuse peritonitis, or is in a state of collapse, most commonly caused by the rupture of an abscess, that I feel warranted in offering this suggestion.

Inflammation in the right iliac fossa, associated with lesion of the cecum, the vermiform appendix and adjacent tissues, can be divided clinically into two classes, namely, intra-peritoneal and extra-peritoneal. The former includes the cases referred to in the text-books as those of appendicitis, typhlitis and peri-typhlitis. I propose the term intra-peritoneal inflammation to include all cases of inflammation in the right iliac fossa having their origin within the peritoneum and associated with lesion of the cecum or the appendix, for the following reasons: 1. I believe it impossible to differentiate between appendicitis, typhlitis and peri-typhlitis. 2. I believe the terms typhlitis and peri-typhlitis to be misleading, and so long as it is taught that they are distinct affections, independent of trouble with the appendix, will the physician be misled. As a result of this classification, there is delay from day to day, in the hope that the case is one either of typhlitis or peri-typhlitis, and that operation is not so urgently called for as were the case one of appendicitis. I consider it nothing more than a mere refinement to divide inflammation of the cecum, as is done, into inflammation of the gut proper and inflammation of its serous covering (peri-typhlitis). I cannot see the practical value of such a division, as both conditions require a common treatment, and further, I do not believe it possible to make the differentiation at the bedside.

It has been my fortune to have seen a large number of cases of inflammation in the right iliac fossa, as well as to have operated on many, and I think I have clearly demonstrated that the best classification of the three pathologic conditions, appendicitis, typhlitis and peri-typhlitis, is under the head of intra-peritoneal inflammation in the right iliac fossa. In the greater number of cases of inflammation in the right iliac fossa the vermiform appendix is the organ primarily attacked; yet there are cases, as has been demonstrated post-mortem, in which the cecum alone is the seat of the trouble. Again, I believe, as do most observers, that when post-mortem both the cecum and the appendix are found to have been the seat of inflammation the starting-point has been in the appendix. Granting, then, that there are three pathologic conditions included in intra-peritoneal inflammation in the right iliac fossa, and that it is only in exceptional cases that the diagnosis between typhlitis and peri-typhlitis can be made, is it not safer and more rational to dispose of all three conditions as one? The differentiation is to be compared with the attempt to recognize the different coverings of the strangulated hernia: while anatomically there are several coverings, these are practically indistinguishable. The differentiation between typhlitis and peri-typhlitis, I think, requires an astuteness greater than we are willing to concede even to the most expert.

Extra-peritoneal inflammation in the right iliac fossa includes the class of cases in which the tissues adjacent to the cecum and the appendix are involved and constitutes para-typhlitis. While I do believe that there are cases of extra-peritoneal inflammation (para-typhlitis) that originate independently of any trouble in the appendix, and involve simply the connective tissue adjacent to the cecum, I do not deny that the starting-point of such an in-

[1] Read at the Twelfth Annual Meeting of the Lehigh Valley Medical Association, held at Bethlehem, Pa., July 7, 1882.

flammation may not be in the appendix. The latter condition may arise when the appendix is an extra-peritoneal organ, as when it lies posteriorly to the cecum and the ascending colon. When the appendix is post-cecal, as well as post-colic, and is the seat of ulcerative inflammation, it is readily understood how, by extension by continuity of tissue, the inflammatory process may involve the connective tissue adjacent to the appendix, and thus occasion a so-called para-typhlitis. This anomalous position of the appendix, when the seat of perforative appendicitis, further accounts for extra-peritoneal collections of pus in the right iliac fossa due to appendicitis and not (in every instance) consequent solely upon inflammation of the connective tissue in the neighborhood of the cecum. It likewise explains why abscess, the result of an appendicitis, does not always point internally to the anterior superior spine of the ilium, but may from its position simulate peri-nephric or lumbar abscess. An intra-peritoneal inflammation starting as an appendicitis and forming a circumscribed swelling, shutting itself off from the general peritoneal cavity by the formation of adhesions, may go on to pus-formation and even rupture into the peri-cecal and peri-colic tissues.

With a knowledge that all inflammations in the right iliac fossa associated with lesion of the cecum, the vermiform appendix and the adjacent connective tissue are divisible into intra-peritoneal and extra-peritoneal, our first duty is to distinguish between them. This we will do under the following heads: 1. *History.* 2. *Symptoms.* 3. *Physical Examination.*

HISTORY.

Extra-peritoneal Inflammation.	*Intra-peritoneal Inflammation.*
Usually constipation.	Constipation the exception rather than the rule.
Very slow onset, particularly if not caused by injury inflicted from without.	Onset sudden.
	There may have been one or more attacks before. Likely to follow a very heavy meal, eaten in a hurry, or the ingestion of indigestible food.

SYMPTOMS.

Pain confined in great measure to the outer part of the iliac fossa in the line of the loin. Constitutional disturbance not at all pronounced early. Disposition, when standing, to incline to the right side, soon followed, if the trouble does not abate, by flexion of the thigh upon the abdomen. Numbness and pain in the right leg frequently complained of. When the inflammatory deposit is great enough to exert pressure upon the right iliac vein there will be edema of the right leg.	In most cases, pain at first referred to the umbilical and epigastric regions, but later to the right iliac fossa. Nausea early and very often vomiting, which becomes uncontrollable if the case does not yield to active treatment. Thirst, which may be extreme. Furred tongue. Bowels usually confined, but there may be a slight tendency to diarrhea. The temperature ranges from 101° to 103°, or higher, with a rapid pulse-rate. Here, too, there may be a disposition on the part of the patient to incline the body to the affected side, as well as to flex the limb upon the abdomen. Very often, frequency of urination.

PHYSICAL EXAMINATION.

Extra-peritoneal Inflammation.	*Intra-peritoneal Inflammation.*
Tenderness above the crest and externally to the anterior superior spine of the ilium and in the line of the loin.	General tenderness over the right iliac region is very marked.
	In the majority of cases I have not found the greatest amount of tenderness at any one point in the fossa, as has been described by McBurney. Yet, in a few cases, I have seen it most pronounced at the so-called McBurney point.[1]
Dulness followed by flatness, at first upon deep percussion, and later upon superficial percussion in the line of the crest of the ilium.	Superficial percussion in the very early part of the case yields negative information, while deep percussion will reveal dulness, and later flatness, as the case steadily advances.
If the case steadily progresses, a mass corresponding in position with the area of dulness will be detected.	Palpation detects very decided resistance offered by the abdominal muscles of the affected side.[2]
	In many cases an indurated mass is detected by palpation of the abdominal wall, which, in many instances, is circumscribed, while in others it becomes rapidly diffused, particularly in the direction of the linea alba and of the pelvis.
Digital examination through the rectum yields negative information. Vaginal examination may be of some value, and should at least be made.	Deep rectal, as well as vaginal, examination[3] I do not regard of much diagnostic importance, early in the case at least. In those cases in which the appendix holds its third position, I regard it of value.
If suppuration takes place, it is usually first manifested by edema of the abdominal walls overlying the mass. Fluctuation is more readily made out than in intra-peritoneal inflammation.	Suppuration is not so readily dectected in this as in the extra-peritoneal form, as fluctuation is more difficult to elicit. Yet I have seen it moderately well pronounced many times.
	If the mass can be felt through the rectum or the vagina it is well to palpate the abdominal walls at the same time, and in this way elicit fluctuation.
	Edema of the overlying abdominal walls I have not found present as often in the intra-peritoneal inflammation as in the extra-peritoneal. If associated with the presence of a mass in either variety of inflammation there are decided chills and sweats, it would be very evident that pus is present.

CASE I.—W. R., thirty-eight years old, seen in consultation, presented a swelling in the right iliac fossa, extending backward in the line of the loin; edema of overlying abdominal walls; a rather sharply defined mass. The thigh was flexed on the abdomen. The temperature had been fluctuating

[1] This point I regard as more useful in approximately locating the site of the base of the appendix than as a diagnostic sign. If the inflammation is most intense in the terminal portion of the appendix, as well as in the class of cases in which the appendix is anomalously located, of what value can this so-called point be? I consider it of no significance whatever in helping to arrive at a correct conclusion as to the nature of a given case.

[2] This I regard as an important sign to be considered in the diagnosis.

[3] When I speak of deep rectal examination, I mean introduction of the finger alone, and not the introduction of the hand, as has been suggested. The latter I consider a most deplorable measure.

for several days, and there had been chills and sweats. The history was one of slow onset, with pain in the right iliac fossa, extending to the loin.

A diagnosis of extra-peritoneal inflammation was made, and operation advised. An incision was made in the right semi-lunar line down to the transversalis fascia, which was opened, and the sub-peritoneal fat exposed, when, after a little dissection, carried backward in the direction of the loin, a large quantity of pus was evacuated. The cavity was washed out, drained, and packed with iodoform-gauze.

Palpation of the peritoneum, which was clearly exposed, over the site of the appendix, yielded negative information. Recovery was complete and uneventful.

Case II.—R. B., twenty-two years old, was admitted to the German Hospital for acute abdominal trouble. The temperature was 102°; the pulse-rate 112. The woman had been sick for three days. There was abdominal pain, most intense in the region of the umbilicus; and diarrhea, followed by constipation. The greatest amount of pain was now referred to the right iliac fossa. Examination of the abdomen elicited tenderness, especially pronounced over the right iliac fossa, with the presence of a distinct mass a little above and to the inner side of the anterior superior spine of the ilium. Deep vaginal examination detected a painful mass. Rectal examination was not satisfactory. Operation was advised. An incision was made in the right semi-lunar line, exposing the peritoneum, which on palpation presented the presence of an unquestionable mass. The peritoneum was incised, an abscess-cavity containing the vermiform appendix opened, and the appendix removed. The cavity was washed out, a glass drainage-tube introduced, and the wound packed with iodoform-gauze. Either end of the incision was closed with two sutures. Some days later, this cavity still containing a small amount of pus, a counter-opening was made through the loin into the cavity, and thorough drainage established. Recovery soon followed.

Case III.—M. H., nineteen years old, was seen in consultation. The woman gave a history of having been taken suddenly ill five days previously, with nausea, severe pain in the right iliac fossa, accompanied by constipation. A tumor rapidly developed in the right iliac fossa, which, within thirty-six hours, extended in the line of the linea alba and of the pelvis. At the time of my visit the patient was vomiting almost incessantly, the stomach being practically non-retentive. The abdominal walls were decidedly rigid over the right iliac fossa, with very slight edema, and a diffused mass presenting questionable fluctuation. Rectal and vaginal examination yielded negative results. A diagnosis of intra-peritoneal inflammation was made.

An incision was made in the right semi-lunar line down to the peritoneum, which bulged into the wound, and upon palpation presented a fluctuating mass. The peritoneum was opened, and found to be adherent to the great omentum, which was distributed over the most prominent part of the mass. The incision was carried carefully through the omentum. In attempting to examine the underlying mass with the finger a large abscess-cavity was ruptured, giving exit to a quantity of fecal-smelling pus. The cavity was washed out with warm distilled water, and further examination made with the finger, when the cavity was found to be shut off from the peritoneal cavity by a limiting wall. The appendix could be neither seen nor felt. The cavity was drained by glass and rubber, and packed with iodoform-gauze. Recovery was uninterrupted.

Case IV.—H. J., thirty-two years old, after eating a large quantity of peanuts, was seized during the night with violent paroxysms of pain in the right iliac fossa. Medication was resorted to for a few days without producing any good effect. When I first saw him the abdomen was tympanitic, the walls of the right iliac fossa tense, but not pitting on pressure, and an indistinct mass was discovered. The family strongly objected to operation. On the following morning the patient being worse, with persistent vomiting, I was hastily summoned. A diagnosis of intra-peritoneal inflammation was made, and operation advised. An incision was made in the right semi-lunar line, down to the peritoneum, through which a small tumor could be distinctly seen. The peritoneum over-lying the tumor was incised. The mass was opened, and about one ounce of pus escaped. The abscess-cavity was washed out, when by touch it was found to contain the appendix. The appendix was ligated, and was found to be perforated, as well as containing a small piece of a peanut. The cavity was packed with iodoform-gauze. Recovery ensued.

Case V.—A. M., twelve years old. History of pain in the umbilical region. A tumor was found in the right iliac fossa, extending back into the loin. Resistance was offered by the overlying abdominal muscles. The temperature ranged from 100° to 102.° The patient was seen twelve days after the onset of the trouble with the attending physician, Dr. Stephen R. Ketcham, who told me that, until within a few days at least, he regarded the case as one of appendicitis, of which it had presented all the symptoms. The pain was now referred to the right costo-iliac space, which, when compared with the the opposite side, was found to be bulging, with edema of the overlying integument. Examination further revealed an unquestionable collection in the loin-space. The patient was removed to the German Hospital, where an incision was made in the loin, and a large quantity of fecal-smelling pus evacuated. The cavity was washed out and packed. Two days later the appendix was cast off through the wound with a quantity of fecal matter. A fecal fistula resulted, but spontaneous recovery ultimately ensued. This was in all probability a case of inflammation of an anomalously-placed appendix, resulting in an extra-peritoneal collection of pus, simulating a peri-nephric abscess.

Case VI.—Mr. S., eighteen years old, became suddenly ill, with pain in the right iliac fossa, radiating to the region of the umbilicus. A day later the pain was much more severe, with distention of the abdomen and nausea. The temperature ranged

between 101° and 102.5°. The pulse-rate increased correspondingly. The bowels were moved by Rochelle salts. A mass about the size of an orange was now to be felt in the right iliac fossa. The pain becoming much more severe, and the abdomen enlarging, I was asked to see the case. I found the patient considerably better, the pain much less, the abdomen smaller, the mass less apparent. The man had gotten out of bed, when his bowels were copiously moved; the dejecta, it was stated, contained milk. With this history, I believed an intra-peritoneal abscess of the right iliac fossa to have ruptured into the cecum.

Operation not advised. Recovery ensued.

The use of the exploring or the hypodermatic needle, to determine the presence of pus, I do not think wise or judicious, and I believe it to be capable of doing much harm. It will be inferred that it is difficult to say when a case of inflammation in the right iliac fossa, associated with a lesion of the cecum, vermiform appendix, or the adjacent tissue, demands operation. The decision will be governed by the local as well as the general condition of the patient, and the result obtained by well-directed medical means. If the recently accepted treatment by means of mild purgation with salines, or calomel if the stomach rebels against salines, and the very moderate use of opium if necessary, fails to render the patient comfortable, to allay vomiting, to prevent abdominal distention, to produce liquid evacuations, the temperature remaining high or tending to rise, and the local trouble becoming more pronounced, with increase of abdominal resistance, tenderness, and induration, I at once and unhesitatingly advise operation. Constant retching, increasing abdominal distention, and obstinate constipation, are three conditions that, when associated, warrant immediate interference, granting that the patient's general condition does not contra-indicate interference. There is, I think, already a sufficient number of fatal cases on record in which treatment by opium alone in gradually increasing doses has been adopted in preference to operation, to disabuse the minds of both physicians and surgeons of the fallacy of such a course. After refusing to operate on many cases brought into the hospital in approaching collapse, with a diagnosis of peritonitis consequent upon an obstruction of the bowels, with hugely distended belly, incessant retching, with a history of the bowels not having been moved for four or five days, and death following in from eight to twelve hours, the autopsy showing the abdominal cavity flooded with pus, the vermiform appendix perforated if not gangrenous, the coils of small intestines greatly distended and matted together with layers of fibrinous lymph, I cannot conscientiously form any other opinion than that the attending medical man did not believe in operative treatment, or deferred calling the surgeon until the golden opportunity was a thing of the past. Under circumstances like these, the argument, Why not operate, if the patient is sure to die any way? is often brought forward. In answer to this, all that I can say is that it often requires better judgment to decide when not to than when to operate. The conscientious surgeon should always be willing to take desperate chances if there is the slightest indication of benefit to his patient, but certainly not otherwise.

In cases in which the symptoms and the local conditions are relieved by the treatment I have suggested, surgical interference should certainly not be considered. I recently operated upon a case of extra-peritoneal inflammation, with suppuration, referred to me by my friend, Dr. Charles Styer. Fluctuation being most pronounced in the loin, I carried my incision through this part and evacuated a considerable quantity of fecal-smelling pus. As the case was originally believed to be one of inflammation of the appendix, I exposed the appendix by an incision in the right linea semilunaris, when both appendix and cecum were found to be perfectly normal. This case, as well as others upon which I have operated, demonstrates beyond doubt, to my mind at least, that we meet with cases of extra-peritoneal inflammation associated with the bowel, arising independently, and not caused by intra-peritoneal irritation. This being so, is it not unwise to argue that every case of inflammation in the right iliac fossa arising in connection with the bowel, and going on to pus-formation, should be subjected to laparotomy? I am, therefore, forced to believe that the operative technique, as I have described it, is the safer procedure in dealing with inflammation of the fossa when it is impossible to say whether it is intra-peritoneal or extra-peritoneal, as is so often the case.

The operative technique for the relief of inflammation in the right iliac fossa associated with lesion of the cecum, vermiform appendix and adjacent connective tissue consists in exposing, first, the transversalis fascia and the sub-peritoneal fat, through the right linea semilunaris by a vertical incision of from four to six inches in length, the middle of which should correspond with the point at which a line drawn from the anterior superior spine of the ilium to the umbilicus intersects the semilunar line. The transversalis fascia and the sub-peritoneal fat having been exposed, if the inflammation be of the extra-peritoneal variety, and if pus be present, the fluid is very readily evacuated, while, at the same time, if the surgeon prefer, a counter-opening can be made well back in the flank, through which a drainage-tube can be introduced and the cavity thus drained to the best pos-

sible advantage, or the operation may be terminated after the manner of Parker. If the inflammation be of the intra-peritoneal variety, the peritoneum is taken up between a pair of hemostatic forceps and incised, when, if an abscess exists, it is evacuated, and the appendix removed, as the case may be. The abscess having been evacuated and thoroughly washed out, the appendix is sought for, care being taken not to break through the limiting wall of the abscess-cavity, granting that it is shut off by such a wall from the general peritoneal cavity. If the appendix is not to be seen or located, I at once complete the operation by either introducing a glass and a rubber drainage-tube to the bottom of the cavity, around which I pack iodoform-gauze, or simply pack the cavity with gauze, not using any drainage-tube. In the cases not under my care after operation I prefer to use the drainage-tube, and have it irrigated twice daily with Thiersch's solution, which when thrown into the rubber drainage-tube will escape through the glass tube, and *vice versâ*. The case progressing favorably, the gauze need not be removed for two or three days. When suppuration has decidedly lessened, the tubes are removed, the cavity washed out and packed with gauze, and healing by granulation promoted.

In the class of cases in which the general peritoneal cavity is involved, I make further search for the appendix if it is not to be seen or felt at the bottom of the wound, keeping in mind its three relations. Most commonly the appendix lies behind the terminal part of the mesentery, pointing in the direction of the spleen. The second most common position of the appendix is directly behind the ascending colon; in the third it dips down into the pelvis. To ascertain if it occupies the first position, it is necessary to lift up the cecum and the terminal portion of the ileum, when the retro-mesenteric space will be exposed. When it occupies the second position, it becomes necessary to lift up the cecum and probably the commencement of the ascending colon as well; this may necessitate dividing the external layer of the ascending meso-colon, which is selected in preference to the internal layer, as the bloodvessels that supply this portion of the gut are in relation with the latter. When the appendix holds the third position, it is more readily exposed, and in the female it is not uncommon to find it attached to the right uterine appendage. The appendix, having been exposed, is ligated close to the cecum and severed on the distal side of the ligature. It has been suggested to invaginate the stump of the appendix into the cecum, and stitch over it the serous covering of the latter. This procedure I have never had occasion to adopt.

In the event of the appendix having been separated from the cecum by ulceration, leaving an orifice of communication with the latter, I close the opening with two or more Lembert's sutures, if the margin of the opening is not infiltrated to too great a degree to warrant the removal of the diseased portion of the bowel. When the cecum is thus perforated by the separation of the appendix, and its coats are very much diseased, I believe it better practice not to attempt to close the opening, but simply to thoroughly drain the wound. My experience has been that the majority of fecal fistulæ of this character close spontaneously. If they do not, subsequent operation can be resorted to.

In Case V of the series here reported, a fecal fistula resulted, through which the evacuations continued to pass for some days. It ultimately healed without operative interference. The point to be borne in mind in cases of this character is the establishment of free drainage, thus preventing the passage of fecal matter into the peritoneal cavity. The probabilities are that in this class of cases the peritoneal cavity has been shut off from the perforated bowel by inflammatory exudation, thus explaining why recovery so often takes place under such circumstances.

From what I have said regarding the operative technique, it will be inferred that I disapprove of meddlesome interference, by which I mean, making a prolonged search for the appendix when it is not readily found. I have seen patients practically disemboweled in an eager search for the appendix, and even then it was not discovered. We know that prolonged exposure of the bowels is attended by profound shock, and is to be avoided if possible. The success of abdominal operations in general depends upon their being done with as much rapidity as possible, granting, of course, that every care is taken in each step of the operation. In work of this character I also disapprove of the introduction of the entire hand into the abdominal cavity, believing that, in the majority of cases at least, two fingers, the index and the middle, with, in some instances, the assistance of one or two fingers of the opposite hand, are sufficient to accomplish all necessary manipulation. We have all seen a sufficient number of cases of laparotomy for the removal of diseased uterine appendages, particularly cases of pyosalpinx, to know that the skillful surgeon accomplishes the removal with but two fingers; this holds good in cases of the character included in the subject of this paper.

The after-treatment consists in the administration of occasional doses of salines or calomel, depending upon the retentive power of the stomach, in order to have the bowels freely moved two or three times daily, and, if the patient suffers much pain, a small amount of opium. I do not

believe in the exclusive use of salines, both before and after operation, in cases in which pain has been an important factor, but I likewise give anodynes, being governed by the amount of suffering. On the other hand I very much disapprove of giving enough opium to mask the symptoms of the disease, as I regret to say is so often done. (Paralytic distention of the bowel, a most unfortunate complication in cases of advancing intra-peritoneal inflammation, is certainly favored by the administration of opium, when given to the extent of producing its physiologic effect.) Opium has held very much the same relation to abdominal troubles in the past as has blood-letting in the acute sthenic inflammatory affections. Both are still useful when properly employed. While I appreciate that opium not administered very cautiously in these cases is harmful, yet I do believe that restlessness and sleeplessness will be more hurtful to the patient than a judicious dose or two of the drug. On the other hand, active purgation by means of drastic cathartics, such as podophyllin and others of its class, I equally disapprove of, as I feel that the excessive peristalsis that is certainly brought about by these agents aggravates the local condition. I have said nothing about suturing the abdominal wound. This I do not approve of, with the exception of one or two sutures at the angles of the wound. In other words, I rely upon healing by granulation. I have found that ventral hernia is not any more likely to follow when the wound is treated in this manner than when it is sutured.

In my earlier operations for the removal of the appendix, in which I closed the wound with sutures, I made a counter-opening in the loin and introduced through drainage. By treating the wound by the open method this is not necessary.

SOME SUCCESSFUL METHODS OF TREATING ALOPECIA AND ALOPECIA AREATA.[1]

BY A. H. OHMANN-DUMESNIL,
PROFESSOR OF DERMATOLOGY AND SYPHILOLOGY IN THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.

ALOPECIA and alopecia areata are diseases of the scalp that have always interested dermatologists. Their study has of late years received a new impetus by reason of careful investigations to which they have been subjected. The questions that have been mostly considered are the etiology and the treatment of these conditions. These are to a great degree independent, and for that reason it may not be regarded as inopportune to devote a few words to the consideration of the etiology before entering upon the subject-matter proper of this paper.

[1] Read in the Section of Dermatology and Syphilography of the American Medical Association, at Detroit, June, 1892.

In regard to the etiology, there exists considerable difference of opinion, and the advocates of the different theories advanced may be roughly divided into three groups, viz.: Those that contend that all cases of alopecia are of parasitic origin; those that contend that the origin of these troubles is of a neurotic character; and those that are inclined to favor the one or the other, according to the particular indications presented in each individual case. The upholders of the parasitic theory have apparently made out a strong case, but their arguments possess certain inherent defects of such a nature as to considerably invalidate their claims. The evidence is, in a large number of instances, far from convincing, and we have added to this the suppression of the negative cases, or of such experiments as do not tend to support the view advanced. The fact that strong antiseptics, locally applied, tend to promote a growth of hair is no proof that the result is due to the destruction of parasites or of pathogenic microörganisms. The further fact that these applications must be of considerable strength seems to invalidate the position still more; for it can be justly argued that the growth is due, not to the parasiticidal properties of the remedy, but rather to its stimulating qualities. Again, we have had exhibited to us cultivations of organisms obtained from such cases. Unfortunately for the cause advocated, these cultivations have but too often proved to consist simply of saprophytes, and could be obtained from organisms found on perfectly healthy scalps. I do not intend to deal exhaustively with these defects in the matter of proving the opinion advanced, but I merely desire to point out some possible sources of error to which investigators have been blinded by their enthusiasm.

Those that contend that alopecia and alopecia areata have a constant neurotic basis have a certain number of objections to contend with that they have not yet successfully overcome. They have very plainly demonstrated that in a certain number of instances the parasites are not the cause. They have also proved experimentally that lesions of certain nerves are followed by alopecia; but in some cases all of the neurotic phenomena discoverable have been treated with no beneficial results, even when aided by external stimulating measures. No results could be obtained until strong parasiticides were employed, and, while claiming merely stimulating properties for these agents, the obvious conclusion could not but force itself upon an impartial observer that the disease was, in fact, of parasitic origin. I do not desire to dilate further on this point, but will pass on to that class of observers whose conclusions appear to me to be not only more rational but correct and in consonance with clinical and pathologic observation, besides being confirmed

by the therapeutic results obtained. I refer to those whose contention it is that alopecia and alopecia areata may be due to either parasitic or to nervous influences, or to both combined. Those that persisted in one plan of treatment have been mortified by observing that failure followed their best efforts. Certain objective symptoms will serve to differentiate alopecia of neurotic and of parasitic origin.

In referring to alopecia in this paper I do not include the senile form, nor that in which the follicles of the hair have been destroyed, atrophied, or lost beyond redemption, but rather to pre-senile alopecia, defluvium capillorum, and alopecia areata. In the last-named affection we find the neurotic and parasitic types rather plainly differentiated by their respective histories and objective characteristics. In the parasitic form a history of infection may or may not be obtained. The disease may be traced to the barber's brush, infection from caps, hats, etc., worn by other individuals suffering from the same trouble, or there may be nothing definite in this respect. More or less marked itching will be present. The history of the attack will show that the falling out of the hair was gradual and peripheral. On inspection the involved area does not present a smooth surface. It is roughened to a certain degree, and the hairs at the border are lacking in luster and are easily broken upon attempts at extraction. Those portions of the scalp most often scratched are involved, and include the temporal and occipital regions, with occasionally the vertex. In many cases auto-inoculation can be clearly made out, and the entire evolution of the trouble traced upon the scalp of the individual. Scrapings from an affected area, if carefully rubbed into the skin of a dog, will produce an analogous condition, thus verifying in a satisfactory manner, the positive character of the cause of the alopecia. It must always be remembered, however, that these conditions apply to cases that have not been tampered with.

In the neurotic variety of alopecia areata, which, in my experience, occurs more frequently than the parasitic, we may or may not have a history of neuralgia, traumatism, or nervous or mental shock. The subjective sensations, if any exist, are not sufficiently well marked to attract much attention. The history is generally that the onset has been sudden, one or several areas becoming suddenly denuded of hair. These may be roundish or oval, or of irregular contour. The sizes of these areas vary considerably, and while progressive to a certain extent, there is a stationary period and an effort at spontaneous recovery. Objectively, the denuded spots have a white, almost glistening appearance, the comparison to ivory being a most apt one. A peculiarity present in this disease is that it is not limited to the scalp, but may attack, as it often does, the eyebrows, the axillæ, the breast, and the pudenda. The few symptoms enumerated are sufficiently well marked to distinguish the conditions from those of parasitic alopecia. We are, however, sometimes called upon to treat cases of alopecia areata in which both a parasitic and a neurotic cause are at work. In these the mixed effect may frequently be observed quite readily; while in the other case the problem presents such complications as to require fine discriminative powers, as well as close observation and examination.

It is hardly necessary to allude to any considerable degree to the other forms of alopecia that I have mentioned. The same general conditions and appearances exist, *mutatis mutandis*, as in alopecia areata. Concomitant phenomena are always found in connection with each individual case, of such a nature as to lead to a tolerably accurate conclusion in regard to the etiology. The cause being recognized, the rational method to pursue readily suggests itself, and the therapeutic succcess will wholly depend upon a proper selection of the remedies, and the method of their application.

I shall now consider some of the successful methods that I have employed in the treatment of some cases of alopecia and alopecia areata. I shall speak of methods, without entering into a detailed recital of cases. I only propose speaking of alopecia areata and of pre-senile alopecia, as furnishing by far the greatest number of cases of falling out of the hair that I have had occason to treat. The cases of pre-senile alopecia that I have treated, exclusive of such as were of syphilitic origin, occurred in males, and the majority of these were light blondes. In all cases, the hair was fine and silky and the scalp rather pale. In some, seborrhea existed, and the amount of secretion varied from very small quantities to quite a considerable quantity. In all, there was a history of more or less itching and of a gradual loss of hair, chiefly at the angles of the forehead and at the vertex. On combing the hair, it could be seen that this loss was considerable, although a considerable portion of what remained consisted of bed-hairs, so that the actual was by no means equal to the apparent loss. All were individuals otherwise in apparent health, whose functions in general seemed to be in perfect condition, with the possible exception of one. The nervous system lacked that stability and repose which should exist in the normal individual and which is so essential to proper assimilation. While this condition was not so apparent in all, those that did not exhibit the grosser phenomena of nervous disturbances exhibited psychic phenomena plainly indicative of nervous instability. Irritability upon slight provocation, anxiety concerning trivial affairs, depression of spirits out of proportion to the exciting cause, and similar pertur-

bations showed themselves as evidence of the neurotic condition present in the individual. A prominent feature was the hopelessness of the patient as to the ultimate result in the treatment of his case.

It will be readily seen that such cases are not very promising, yet a little moral suasion has quite an effect in improving the condition, and success is not the impossibility it might at first appear to be. The general treatment that I have adopted has been various in different cases, but has been directed to the amelioration of the condition of the nervous system. In some cases I have ordered the following twice daily in pill or in capsule:

℞.—Strychninæ sulphat. . . gr. $\frac{1}{60}$.
Ferri redacti . . . gr. j.
Quininæ bisulphat. . . gr. j.

Or, if starvation of the nerves seemed to be present, compound syrup of the hypophosphites was ordered in dram-doses four times daily, with a milligram (gr. $\frac{1}{62}$) of strychnine sulphate with each dose. In some cases, I have found it advantageous to supplement this treatment with pilocarpine hydrochlorate, taken at bedtime, gr. $\frac{1}{8}$ or gr. $\frac{1}{6}$ in powder. The effect of this internal medication was not a matter of coincidence, for, by its alternate withdrawal and resumption, most notable differences could be observed. These differences were so marked as to attract the attention of the patients and lead them to the conclusion that the internal medication was most beneficial in the improvement of the local condition. Such results occurred not only in one case but in several, and, although failure might follow the same course in some future cases, the success that has been attained is sufficiently encouraging to justify a continuance of the method until a better one can be suggested that will stand as rigid a test.

Alopecia areata occasionally presents difficulties of such a nature as to almost make us despair of any successful issue. I have been extremely fortunate in securing good results, and can only attribute them to the energetic means that have been used. Before entering into a consideration of the treatment, I desire to premise that I have always been careful to distinguish between the parasitic and the neurotic varieties of the affection. Having done this, the treatment was adapted to the condition present, and, while one method might fail, the general principle was always kept in mind in the application of the treatment.

In the parasitic form of alopecia areata I have used two parasiticidal mixtures; one, the weaker, for application to the entire scalp, to prevent new infection and a further spread of the trouble; the other, the stronger, for application directly to the implicated areas, for the purpose of destroying the parasite, and thus bringing the disease to an end. Both preparations were ordered to be applied twice daily, and, as all the cases I observed occurred in males, I had the hair clipped close to the scalp, thus facilitating thorough application of the remedy. For the weaker application I first used a 1:750 solution of mercuric chloride; afterwards a 3 per cent. solution of creolin. Both acted well, and the only advantage of the latter is the smaller danger of intoxication. This wash is to be applied to the entire hairy scalp, the affected areas being attended to after the first operation has been concluded. For the affected areas I ordered the application of sapo viridis for about five minutes, then gentle scrubbing, followed by:

℞.—Hydrarg. chloridi corros. . gr. j.
Lanolini . . . . ℥j.
M. Tere bene.
Sig.—Apply twice daily in small quantity.

In a comparatively short time a strong, healthy growth of hair could be observed. It is not always necessary to make this application twice daily. The frequency can be easily determined by the observer. Not infrequently one application a day, or every other day, will, in a short time, be all that is necessary. I have had no occasion to change the composition of this application, as in the few cases in which I employed it it proved satisfactory.

In alopecia areata of neurotic origin, which, in my experience, occurs much more frequently, I have given internal treatment in some instances and not in others. After trying various internal remedies, with more or less success, I have finally adopted the same preparations as those I have spoken of in the treatment of pre-senile alopecia. They have seemed to serve the best purpose and gave the best final results. I have observed that this internal treatment is of positive and undoubted benefit. Discontinuance of the remedy is followed by inferior results, and the effects of resumption of the treatment become very quickly apparent. In some cases, however, general treatment appears to be entirely unnecessary, but I have found these to be very few in number. They appear to be those in which a general shock had been experienced as a result of traumatism, and the nervous equilibrium was regained in a comparatively short period of time. Even in these, if no form of treatment has been employed for a considerable period of time after the injury, internal treatment is found of benefit. Yet cases of the last class must of a necessity be very infrequent. In those experimental cases in which nerves have been excised and the operation was followed by alopecia areata, the regeneration of the hair occurred spontaneously, and local as well as general treatment appeared unnecessary, but such cases would not serve as a criterion.

In the local treatment of alopecia areata the methods that I have found successful are essentially of the same character, although they differ materially in application. I do not claim any originality for either, as one is rather old and the other was suggested some little time since. Both are essentially irritant in nature, but efficient so far as my experience enables me to judge. The first is the suggestion of a French author, and consists in applying cantharidal collodion to the affected area. After vesication has been established, a dressing of some bland ointment is applied. As is well known, cantharidal collodion varies much in composition. In some instances it acts very promptly, while in others its action is quite slow. Again, its effect in the same individual may be comparatively superficial or quite deep, depending upon the proportion of cantharides present and the activity of the fly used in its composition. These circumstances necessarily act as factors in controlling the frequency of application of the remedy. In some cases I applied the cantharidal preparation twice a week, and in others it could be used but once in the same time. The reaction was more or less prompt, and, in some cases, I have had the unfortunate experience of seeing no effect of a distinct character, beyond some mild superficial irritation. However, by obtaining a good article, I have been enabled to obtain excellent results in a comparatively short time. While the effects produced were of the best, the various inconveniences attending the use of cantharidal collodion made the method anything but a pleasant one to the patient. The method is not easy of management. It causes matting of the hair; the application does not look well; it is very difficult to remove, and is inconvenient to handle. Added to this, the disagreeable necessity of continuously applying an ointment further increases the aversion of patients to the entire local curative procedure. I have often experienced much difficulty in persuading patients to continue the treatment, and it was only the good results obtained that led them to submit to it, in the hope of a speedy recovery and a proportionately short submission to the entire process. This difficulty was particularly marked in females.

When a new method was announced, obviating many of these inconveniences, and for which superiority of results was claimed, I immediatety adopted it, and desire here to express my complete satisfaction with the results attained by its use. I allude to the application of pure carbolic acid as advocated by L. Duncan Bulkley. He advocates the application of pure carbolic acid to the affected areas once every two weeks. The extent of surface to be thus treated must not exceed two square inches. He furthermore states that two, or at the most three, applications will suffice to effect a complete return of the hair. It may be Bulkley's experience to have had tractable cases, or I may have been unfortunate to have had only stubborn ones. This much, however, is certain: As soon as the method was announced it struck me as a particularly good one to use. I had a patient to whom it was applied as directed, but I had no success. This led me to modify the treatment, as follows: Instead of making an application once every fortnight I made it twice a week, and instead of limiting it to two inches I applied it to the entire surface involved—about ten square inches. Moreover, I was not at all satisfied with the ordinary 95 per cent. carbolic acid that I could obtain. It did not seem to be sufficiently strong. I secured some pure English carbolic acid, and by this means obtained more rapid and marked effects. With this product it is unnecessary to rub forcibly into the skin, and the result obtained appears to me to be much more rapid. It is true that my experience thus far has been limited to but a few cases, but they have proved so satisfactory that I shall continue until something better is offered. The method of applying the agent consists in freely swabbing the affected area with it, no matter how much of the scalp is involved. Those portions to which the acid is applied turn milky-white in a few moments, and if any are not thus affected they are touched again. This is all that is necessary. If any parts that turn white show marked inflammatory reaction, they are passed over at the next sitting. Generally, however, there is at most but a slight amount of desquamation.

Such treatment, while rather painful, is efficacious. I have also been in the habit of employing it in presenile alopecia in a modified manner. Instead of applying the carbolic acid liberally I have done so sparingly and at intervals of one and two weeks. The impulse given to the growth of hair by this procedure was quite noticeable.

That the methods that I have described are infalliable I certainly do not wish to claim, but that they are sufficiently rational to induce a trial I hope has been shown in the foregoing paper. They have been successfully employed in quite a number of cases.

CLINICAL MEMORANDA.

GONORRHEA OF THE VESICULÆ SEMINALES.

By C. S. HOFFMAN, M.D.,
of Keyser, W. Va.

From a case that I have had under observation for the last eighteen months I have felt satisfied that there is a disease of the seminal vesicles which has not yet received the degree of attention that it should, and an article published in The Medical News of May 7th, by Dr. F. B. Robinson, of Chicago, has led me to publish the following case:

In September, 1890, I was called to see Mr. L. A., fifty years old, married, and with whom I was well acquainted. He had always been very stout and hearty. He had never had any disease of his genito-urinary apparatus. I found the man suffering with a severe attack of gonorrhea, with epididymitis and orchitis of the left testicle. The gonorrhea was of about two weeks' standing; the orchitis and epididymitis of about three days' standing. The constitutional symptoms were such as would naturally accompany this combination of diseases. There was pouring from the urethra a copious muco-purulent discharge. No microscopic examination of the pus was made, but there could be no question from the history of the case, the symptoms, and discharge, that the disease was anything but a virulent case of neglected gonorrhea.

The gonorrhea yielded to treatment very slowly, from eight to ten weeks elapsing before the discharge had finally ceased. The inflammation of the testicle and epididymis subsided in from seven to ten days, although the man at times yet complains of pain in the testicle. After the acuteness of the attack had somewhat subsided, another source of annoyance developed in the form of a heavy, aching pain located deeply in the perineum. The pain was described as a sore, heavy, aching feeling, especially aggravated by standing for any length of time. It was also increased when the rectum became full of feces. The patient could hardly sleep at night until toward morning, when he would get somewhat easier. He could not sit flat down on a chair, owing to the aggravation of the pain by the pressure. The pain would be very annoying for one, two, or three weeks, and then there would sometimes be an intermission of a few days of less suffering, but never entire relief. For the first week or two after this last trouble developed, micturition *may* have been somewhat more frequent; on this my notes are deficient; but after this date the urine was not passed oftener than natural.

Supposing, from the symptoms, that inflammation of the prostate gland had developed, I employed appropriate treatment for some time without any improvement. On making a careful examination with my finger in the rectum, I found the prostate gland perfectly normal in size and not painful to pressure; but just back of it I could, on each side of the base of the bladder, clearly distinguish two bodies, longer than wide, which corresponded in location with the seminal vesicles, and which were exquisitely sensitive to touch. With a sound in the bladder and my finger in the rectum, I could positively locate them. Moving the sound in other directions in the bladder and pressing against it with my finger in the rectum would occasion no suffering, even when I would press the prostate gland between the two; but as soon as I would catch the seminal vesicles between the sound and my fingers, the patient would give indications of intense pain. Notwithstanding all that I could do in the way of treatment, the man made but very little improvement. He was, however, able to keep at work as a carpenter, though with much suffering, and he would occasionally have to stop for a day or two and lie down. In the spring of 1891, I advised him to consult a celebrated professor of surgery in one of our best medical schools for examination and treatment. He returned, saying that the professor made three examinations, and told him the disease was an inflammation of the base of the bladder, and for the cure of it prescribed salol and oleoresin of cubebs in capsules three times a day.

From this treatment the man derived no benefit, although he gave it a thorough trial. I have made repeated examinations with my finger and sound as described, and have always found the prostate gland of normal size and not painful; while reaching further back and pressing on the seminal vesicles, the pain was very acute, and especially so on the right side. I could never detect any fluctuation. To touch, the vesicles appeared swollen and harder than it appeared to me they should be in health. At present, this man is not entirely well, but for the past four or five months he has been gradually improving, and now rarely complains of his disease unless his work requires him to stand much for several days. That this disease was not a disease of the bladder is evident by the absence of trouble in micturition, which was neither frequent nor painful; nor has there been tenderness on pressing the bladder above the pubes, or with the sound in the bladder, except when counter-pressure was made over the vesiculæ seminales.

The prostate gland could not have been the seat of the trouble, else it would have been either enlarged or painful on pressure.

That the seminal vesicles were the seat of the disease is evident from the location, from the sensation and the pain elicited on pressure, and that the inflammation in them was caused by the gonorrhea seems clear from the history of the case. Dr. Robinson says it follows urethritis and generally exists with epididymitis. In this case it followed the urethritis, but did not develop until the epididymitis began to improve.

I find no mention made of any disease of the seminal vesicles in four of the five standard text-books on surgery in my library. Wyeth's *Surgery*, second edition, only mentions "that the inflammatory process may extend to the seminal ducts." In Bumstead & Taylor's work on *Venereal Diseases*, fifth edition, a short article is given to "Gonorrheal Inflammation of the Vesiculæ Seminales," in which the authors rely chiefly upon the statements of others for a description of the disease. In the course of this article it is said: "Inflammation of the vesiculæ seminales can rarely be diagnosticated with absolute certainty during life;" while I feel from the history of this case, as I have here related it, that with care it *is* possible to arrive at a correct diagnosis.

From a careful study of this case I have been impressed with the conviction, and especially since reading the article of Dr. Robinson, that gonorrhea of the vesiculæ seminales is probably of more frequent occurrence than it is recognized to be. The affection is probably often diagnosticated and treated as a disease of the prostate gland or base of the bladder.

A LABOR COMPLICATED BY CONGENITAL HYDROCEPHALUS.

BY OLIVER HOPKINSON, JR., M.D.,
VISITING PHYSICIAN TO THE LYING-IN CHARITY AND NURSE SCHOOL OF PHILADELPHIA.

BY permission of Dr. Thomas Hunter, in consultation with whom I saw the patient, I report the history of a labor complicated by intra-uterine hydrocephalus. The

case is especially interesting on account of the rarity of the complication (occurring, according to the statistics of Madame La Chapelle, fifteen times in forty-three thousand five hundred and forty-five deliveries), of the dangers to both mother and child always involved in these cases, and of the peculiar manner of the delivery of the head. I wish to add here that it was not until after the expulsion of the head that a true diagnosis was made.

We supposed from the large size and perfect form of the child's body that the difficulty was due to a correspondingly large head, with excessive ossification, increased by its position (the occiput was in the left iliac fossa; the chin dipped in the pelvis, with the face in relation with the right sacro-iliac synchondrosis).

There was nothing unusual discovered by palpation except the large size of the head. Both Dr. Hunter and myself can testify to the truth of the following statement of Playfair: "The diagnosis of intra-uterine hydrocephalus is by no means so easy as the description in obstetric works would lead us to believe."

Mrs. X., thirty years old, a quartipara, had a good family history. Her first husband, by whom she had three healthy children, died five years ago of pulmonary tuberculosis. Two years later, she married her second husband, the father of the child under consideration. Her previous confinements had been easy and natural, except the first, which was instrumental; all were vertex presentations.

Mrs. X. enjoyed good health until the beginning of this pregnancy, when she began to lose flesh and strength, with almost constant cough, nausea, and vomiting, and in the latter part with dyspnea that caused much distress—symptoms with which she had not been troubled in former pregnancies. She stated that the nausea, vomiting, and dyspnea were due to the position of the head, which she could feel "below the right breast-bone," and which "sunk in and out" whenever she coughed. About five months ago, Dr. Hunter, being consulted, detected evidences of slight trouble at the apex of the right lung.

The first sign of approaching labor was the rupture of the membranes at 10 P.M. The woman felt no pains until three hours afterward, when she had two or three rather severe ones, by which the breech was expelled. Then the pains left her. Dr. Hunter arrived at 2.30 A.M., one hour and a half after the expulsion of the breech, and found the fetus dead, the body born to the umbilicus, the back anteriorly, the head and arms in the cavity of the uterus, with the shoulders in close proximity to the vulva. With great difficulty he succeeded in bringing down both arms. After making several unsuccessful attempts to deliver by the usual methods he advised a consultation. The application of forceps was impossible from the position of the shoulders. I saw the patient at 5 A.M. Repeated attempts to move the head having failed, we decided to detruncate and apply the forceps before resorting to craniotomy. The neck was severed with a scalpel, and pieces of bone removed as far toward the base of the brain as possible, in order that the soft parts of the mother should not be injured.

The severing of the neck was followed by an escape of fluid (several ounces or more), which we mistook for the liquor amnii—an excusable error, as we did not see from where the water came, the neck being drawn up in the vagina by the great tension. I then tried to apply Tarnier's axis-traction forceps in order to rotate the head to a transverse position—it being still oblique—but failed.

Whilst the craniotomy instruments were being procured the patient had about an hour's rest, with good effect; for during that time there were several good pains—the first since the birth of the breech—which caused a favorable change in the uterus. Preparations were now completed for craniotomy. Dr. R. O. Kevin administered the ether. I found the uterus smaller and harder, the chin and mouth lower in the pelvis, but the occiput was still resting upon the ilium, with the neck high up behind the symphysis, the suboccipito-frontal diameter in correspondence with the right oblique pelvis. This change induced us to make one further effort with the forceps, which was easily adjusted to the sides of the head, and, by traction combined with compression (such a degree of force and compression being used as were considered justifiable and safe), the head was brought down, till the chin (still posterior) touched the pelvic floor.

Meeting with resistance, the instruments were removed, it being decided to leave the termination of the case to Nature, or, if that failed, to resort to craniotomy, which would now be comparatively a safer and easier operation, for both the pelvis and vagina were capacious. Happily, the pains increased in force and frequency, and with constant supra-pubic pressure the chin began to rotate anteriorly, sweep over the perineum, and glide under the symphysis—the mouth and nose at the vulva.

There being now a delay, notwithstanding several good pains, grasping the chin with the placenta forceps, I made traction directly upward during the following pain, when the forehead, occiput, and neck were born successively. The neck underwent a complete revolution. Probably ten minutes elapsed between the removal of the forceps and the birth of the head, which occurred at 7.30 A.M., six and a half hours after the birth of the breech.

The cause of the engagement of the face seems to be that, after the severing of the neck and the escape of serum, which the pains, with supra-pubic pressure, hastened, the suboccipito-frontal, biparietal, and bitemporal diameters, the ones chiefly concerned, were lessened by the collapse of both parietal bones.

Dr. Hunter informs me that the convalescence was unattended by any abnormal pelvic symptoms, but that the pulmonary complication has rapidly and decidedly advanced.

The etiology of intra-uterine hydrocephalus is obscure. I can find no cause in this case, unless it be the tuberculous condition of the mother.

MEDICAL PROGRESS.

Twelve-pound Fibroma of a Labium Majus.—At a meeting of the Medical Society of the State of Washington, McKone reported the case of a woman, thirty-nine years old, in the fifth month of pregnancy, who presented a large tumor of the left labium majus that had been

present from the ninth year of age. The mass had slowly increased in size; but only within a year had it occasioned any pain. It was as large as a man's head, and was attached by a short pedicle. The posterior aspect of the tumor was discolored and suppurating; two glands in the adjacent groin were enlarged and tender; there were pain and vomiting; the temperature had risen; and the pulse was accelerated. It was decided to remove the growth, and the woman acquiesced in the proposition. A rubber ligature was placed around the base of the tumor and another around the pedicle as close to the body as possible, and a careful dissection made of the intervening pedicle. The tumor was then severed from its connections. The patient made an uninterrupted recovery, and at term was delivered of an eleven-and-a-half-pound baby. On microscopic examination the tumor proved to be a fibroma.

Psoriasis.—DUBOIS-HAFENITH (*La Policlinique*, 1892, No. 6, p. 81) thus summarizes his views upon the subject of psoriasis: Psoriasis is a distinct affection, a morbid entity. The designations lingual psoriasis and syphilitic psoriasis are inappropriate and tend to lead to confusion. The etiology and pathogenesis of psoriasis are still obscure—that is, there is yet no causal treatment. Psoriasis is incurable, in the sense that there is no method capable of preventing recurrence. Arsenic is not a specific for psoriasis; neither is potassium iodide. The greatest reliance is to be placed upon the local treatment; general indications are, however, not to be ignored. The best remedy is chrysophanic acid; next in value come pyrogallic acid, oil of cade, naphthol, and white precipitate. In a general way the choice of the remedy and of the method will depend upon the social position of the patient, and the seat and extent of the disease. The individual tolerance of the skin is also to be considered. A certain number of cases of psoriasis resist all methods of treatment.

Oil of Anise as an Imbedding Medium for Making Frozen Sections.—To overcome some of the difficulties attendant upon the ordinary use of the freezing microtome, KUHNE (*Centralbl. f. Bakteriol. u. Parasitenk.*, 1892, xii, 1, p. 28) recommends the employment of oil of anise as an imbedding medium. Thin sections of hardened tissue, freed of their alcohol, are placed in a sealed flask containing oil of anise and permitted to remain for from twelve to twenty-four hours. They will then freeze readily, and delicate sections can be made. These are taken from the knife and placed in a dish containing oil of anise. Thence they are transferred to absolute alcohol, and are ready to be stained.

Peritonitis Due to Gonococci.—WERTHHEIM (*Centralbl. f. Gynäkol.*, No. 20) has reported the case of a woman, twenty-four years old, who for three years had a vaginal discharge, with pain in the hypogastrium. A right-sided salpingitis and a recent perimetritis were found. Ordinary treatment not availing, celiotomy was resorted to and the diseased appendages removed. In the pus contained in Douglas's cul-de-sac large numbers of intracellular gonococci were found. The right tube was evidently the source of the inflammation.—*Wiener medizin. Presse*, 1892, No. 25, p. 1018.

THERAPEUTIC NOTES.

Galvanism in Gynecology.—As the outcome of an experience of four years, RUTHERFORD (*Practitioner*, July, 1892, p. 32) has arrived at the conclusion that in the treatment of diseases of the female pelvic organs, the utility of the employment of galvanism, except in cases of fibroids, has been overrated, and that the results are not sufficiently satisfactory to command confidence. In uterine fibromata, this method of treatment is satisfactory in a few carefully selected cases only; as when hemorrhage is the chief or only symptom and in rapidly growing interstitial fibroids. The galvanic current merely acts as a caustic, destroying or diminishing the vascular areas that surround and constitute the source of nutriment for the fibroids. The primary polar action that abstracts acids and bases at the anode and kathode is too slight to be of any real benefit. The interpolar action is still an hypothesis.

Traumatic Tetanus Cured by the Antitoxine Isolated by Tizzoni and Cattani.—TARUFFI (*Riforma Medica*, No. 90) has reported the case of a peasant, seventy-four years old, who, ten days after receiving a lacerated and crushed wound of the right little finger while loading wood, presented manifestations of tetanus. For two days the symptoms increased. Then 0.25 of antitoxine that had been obtained by Professor Tizzoni from the blood-serum of an immunified dog was injected subcutaneously, and again twice on the following day and the next succeeding day, and once a day later—six injections in all being given.

The patient began to improve after the first injection, and on the eleventh day was entirely well. Virulent tetanus bacilli were found in the amputated finger.—*Wiener medizin. Presse*, No. 23, p. 937.

Treatment of Chorea.—JUMON maintains that the treatment of chorea should be governed by certain well-defined indications. In ordinary chorea, antipyrin and arsenic yield the best results. In chorea of rheumatic origin or associated with rheumatic manifestations, antipyrin is still indicated; with it sodium salicylate may be conjoined; sulphur baths may prove useful. If an hysterical element exist, the bromides may be employed. In chorea of cardiac origin, depressing remedies are to be avoided; potassium or calcium iodide is indicated. In most cases of chorea, gymnastic exercises and reconstructives may be advantageously employed.—*Journal de Médecine de Paris*, 1892, No. 28, p. 335.

Agathin, a New Antineuralgic.—ROSENBAUM (*Deutsche medizin. Zeitung*, No. 50) has successfully employed agathin in the treatment of neuralgia and rheumatism. Agathin is a body chemically related to salicyl and methylphenylhydrazon, and appears in tasteless and odorless leaves, insoluble in water, soluble in alcohol and ether.—*Wiener medizin. Presse*, No. 27, 1892, p. 1100.

Creasote for Whooping cough. — Creasote, in doses of from half a minim upwards, three or four times a day, recommended in the treatment of whooping-cough. The cough diminishes, vomiting is infrequent, and the duration of the attack is abbreviated.—*Lyon Médical*, No. 29.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.
PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, AUGUST 6, 1892.

TIMELY OPERATION FOR APPENDICITIS.

THE question as to the proper time for surgical intervention in cases of inflammation of the cecum, the appendix and the surrounding tissues is one of the most important in practical medicine. Within the last five years much has been written upon the subject. It has been often discussed and still remains unsettled. In America, however, the general tendency of opinion is, we think, more and more in favor of early resort to operative treatment, and less and less to tolerate procrastinating expectancy.

Among those to whom the greatest credit is due for what amounts to a revolution in professional opinion are THOMAS G. MORTON, of Philadelphia, and CHARLES MCBURNEY, of New York. Other surgeons are also worthy of distinguished mention; but recent papers by the two operators named have reawakened a sense of our obligations to them.

MCBURNEY [1] lays great stress upon the importance of what, following Jacobi, he terms "timely" rather than "early" operation. He says: "I am surprised to see in the printed report of the *Proceedings of the Philadelphia County Medical Society*, at a meeting held in September last, that so representative a man as DR. PEPPER said that 'If every case of appendicitis were operated upon, the mortality would be tenfold what it now is.' The mortality is at present over twenty per cent. in cases treated by the expectant plan, so it is very evident that DR. PEPPER'S view of the possibilities of surgery is a very black one. But it is hardly worth while to follow his line of argument, for it seems to be based on the assumption that surgeons wish to operate upon every case of appendicitis. I have never read nor heard that any surgeon has expressed such a wish. My own experience, and that of many others, has been that operation for acute appendicitis, done at the right time and before the disease had progressed too far, is nearly invariably successful. Out of some fifty such cases I have seen only one die. . . . . As regards the diagnosis of the conditions which should lead to operation, I must differ entirely with DR. PEPPER and others who think highly of the method of examining the appendix through the rectum. In the early stages of appendicitis this method has no value whatever. Of course, those who are accustomed to allow abscesses to reach a large size will in time find a bulging tumor low down in the pelvis. We had better devote our attention to learning the signs of suppurative appendicitis before the abscess has threatened the rectum."

To MORTON must be given the credit for having first deliberately sought out and removed an ulcerated appendix,[1] and for having, by his paper before the Philadelphia County Medical Society,[2] first clearly established the principles of surgical treatment of pericecal inflammation. Thus Philadelphia may claim the greater share of the credit for what may justly be called one of the most important and most radical advances of modern surgery. "MORTON'S operation," as it deserves to be called, is a different thing from the procedures formerly in vogue, when the abdomen was simply opened by a "Willard Parker" incision, to drain an evident abscess.

MORTON [3] divides cases of inflammation of the appendix into three groups. The first group is that of cases of simple irritation or inflammation of the appendix, a condition difficult of recognition during

[1] Cases of Appendicitis, Illustrating Different Forms of the Disease." Medical Record, April 16, 1892, p. 421.

[1] Case of Dr. Frank Woodbury reported in the Proceedings of the Philadelphia County Med. Soc., vol. viii, 1888, p. 101.

[2] Proceedings of the Philadelphia County Medical Society, vol. viii, 1888, p. 267.

[3] "On Appendicitis and Peri-cecal Inflammation, with Notes of Cases Illustrating Unusual Difficulties in Diagnosis." Journal of the American Medical Association, July 25, 1891.

a first attack, but which is likely to recur, when the diagnosis becomes strongly probable.

The second group is that of cases of inflammation with ulceration or perforation, in which a protective capsule is formed, so that, unless the walls surrounding the abscess-cavity should yield, peritonitis does not take place.

The third group is that of cases in which ulceration and perforation take place before sufficient lymph-protection has been established. Such cases are early associated with symptoms of unusual depression, and often of profound collapse.

Any case of mild appendicitis belonging to the first group of cases may pass to the second group, and in no case of the third group that MORTON has seen did careful inquiry fail to reveal the fact of a previous attack of appendicitis.

Rarely has a discussion before a medical society been productive of more good than that historical discussion before the Philadelphia County Medical Society on December 14, 1887, for from that discussion may justly be dated the modern advance in the treatment of appendicitis. As was stated, at a later date, by T. S. K. MORTON,[1] "Differential diagnosis of inflammatory affections in the region of the cecum, which is usually impossible prior to surgical interference, is neither necessary nor important, as operative procedure up to the point of establishing a diagnosis is identical for all affections of the cecal region; and the ratio of appendicular to cecal inflammatory affections is probably 100 : 1."

The surgeon last quoted is undoubtedly correct in his unqualified condemnation of needle exploration. "The procedure is inherently dangerous and will furnish no indication that cannot otherwise be obtained." This was demonstrated not long ago at an operation in which the relations of the parts and the situation of the abscess were such that not alone would the exploring needle have failed to reveal the presence of pus, but it would have perforated the gut.

Equally correct is the dictum that operation should be undertaken "not later than the third day of the disease, if the patient up to that time has failed to markedly improve" under skilful medical treatment. "Further than this, we should invariably operate as soon as the presence of pus is assured; when peritonitis is developing or spreading; when signs of sudden rupture of an abscess into the peritoneal cavity appear; and when septicemia from septic absorption is taking place. In children operation must often be performed earlier than in adults, as with them the malady is more speedy in development, more fatal in tendency, and shows a greater proclivity to involve the general peritoneum."

There can be no doubt that an overwhelming majority of cases of appendicitis recover without surgical treatment; according to MCBURNEY, nearly eighty per cent. Nevertheless, it is of the utmost importance that in the treatment of the remaining twenty per cent. a proper time for operation should not be allowed to go by, and thus patients be liable to perish, notwithstanding the untimely surgical intervention.

It is a question requiring the exercise of much judgment, and one in which no man is justified in taking alone the responsibility for delay. KEEN[1] strongly urges physicians to promptly call their surgical colleagues in consultation. PEPPER[2] with equal emphasis insists that the possibilities of medicine must not be forgotten by the surgeon. Both are right. Physician and surgeon both should see the case at the earliest possible moment. The surgeon should call the physician to his aid in order that no therapeutic or diagnostic method, possibly unknown to him, should be omitted in the examination of the case, or in treatment, with the hope of averting operation; and the physician should summon the surgeon in order that the latter should have full knowledge of all the circumstances of the case before taking the knife in hand.

Every case of appendicitis, no matter how mild it may apparently be, involves the possibility of the patient's death. Every operation involves the possibility of unknown and serious complications and of a fatal issue, and no professional pride of opinion, no unworthy motive whatsoever, should prevent that early consultation which alone will insure against both the alternative dangers: on the one hand, that of undue haste in operation; and on the other hand, that of undue procrastination and temporizing after operation has become necessary.

THE SIXTIETH ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

IN another part of THE NEWS we present abstracts of the several addresses delivered in the

[1] Proc. Phila. Co. Med Soc., vol. xii, p. 288. [2] Ibid, p. 287.

various sections of the Sixtieth Annual Meeting of the British Medical Association, held at Nottingham, July 26, 27, 28, 29. Some of the papers are noteworthy, and afford an index of the progress that is being made in the various departments of medicine. The relations between the two continents are so close that little transpires in one that does not early receive critical scrutiny in the other.

The Address in Medicine by Dr. Cuming is a learned discourse, dealing in a masterly way with numerous important questions.

In the Address in Bacteriology Dr. Woodhead ably expounds some of the most recent problems in the new science, together with the practical fruits of their solution.

The comparative observations of Dr. Ransom upon plants, in their application to the process of inflammation, are both ingenious and interesting.

The address of Mr. Croft in the Section of Surgery is a reflex of the work of his section, and deals briefly with some topics of absorbing interest.

Dr. Bevan Lewis in the Section of Psychology makes a practical and thoughtful contribution, indicating a number of innovations that have been introduced in the West Riding Asylum at Wakefield.

In the Section of Pathology Mr. Victor Horsley made a few terse, pointed introductory remarks, defining the almost ignored distinction between pathology and morbid anatomy.

In the Section of Diseases of Children, Dr. Marshall made a strong plea for special instruction in this department of medicine.

In the Section of Pharmacology and Therapeutics Dr. Brookhouse reports seven cases of pulmonary tuberculosis, in which intra-tracheal injections of menthol were practised with satisfactory therapeutic results.

Without being over-sanguine, the future in both preventive and curative medicine is exceedingly assuring.

THE GROSS MONUMENT FUND.

A subscription was at one time made for the foundation of a Chair of Pathological Anatomy, in memory of S. D. Gross. We believe that something like $7000 was subscribed, but that the amount not being sufficient for the purpose, the project fell through. Would it not be well to consolidate this fund with the Gross Monument Fund of the American Surgical Association? This would insure a suitable memorial to Professor Gross.

SOCIETY PROCEEDINGS.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-eighth Annual Meeting, held at New London, Conn., July 20 and 21, 1892.

First Day—July 20th.

The Society was called to order by the Vice-President, Dr. George C. Harlan, of Philadelphia.

The first paper was one by Dr. Charles A. Oliver, of Philadelphia, entitled "History of a Case of Gunpowder Injuries to both Corneæ, Irides and Lenses, with Subsequent Restoration of Vision to almost Full Acuity."

A man, eighteen years old, received the powder-contents of a blank cartridge squarely in the face at a distance of three feet. There were several penetrating wounds of the corneæ, and powder was deposited in both irides and lenses. When seen several hours later, the loose particles of gunpowder were removed from the corneæ, conjunctivæ and sclerotics. The left cornea presented a peripheral wound, with a corresponding tear in the iris, through which a powder-grain could be seen adhering to the lens. Another wound extended almost through the cornea. The fundus was apparently normal. The right eye presented a penetrating wound of the cornea, with injury to the iris. The lens was swollen and rapidily becoming opaque. Four days later, secondary glaucoma developed. Eserine and cold compresses were then employed, and on the following day an iridectomy was performed. The wound healed promptly; atropine was resorted to on account of slight tenderness in the ciliary region. The left eye improved continuously. When the patient was discharged, two months after the accident, there was good perception of light in both eyes. In the left eye there was considerable unabsorbed lens-matter. The tension of the right eye was normal; most of the lens-matter seemed to have been absorbed. The lower half of the pupil was covered by a thin opaque sheet of capsular débris. Two weeks later, a broad round hole was made in the lower half of the capsule, securing, with proper correction, vision of $\frac{5}{7}$. After free double discission of the left lens, vision was restored to $\frac{5}{10}$. A year later, the eyes were perfectly quiet, and the patient pursued his ordinary occupation.

Dr. Samuel Theobald, of Baltimore, read a paper entitled "Removal of a Fragment of Steel from the Vitreous Chamber by Means of the Electro-Magnet, with Preservation of Nearly Normal Vision." A small piece of steel had passed through the cornea and iris near the periphery, but had fortunately missed the lens. On the eleventh day, an attempt was made to extract the foreign body, which had excited a high degree of inflammation. The clouding of the vitreous humor prevented its location with the ophthalmoscope. A longitudinal incision, about 4 mm. long, was made through the sclerotic and deeper coats, between the inferior and external recti muscles and back of the ciliary body, through which the magnet-point, sterilized by boiling water, was introduced into the vitreous chamber. After several unsuccessful attempts, the bit of steel was withdrawn, adhering to the magnet-point. There was considerable hemorrhage, but no loss of vitreous. Subsequently a lotion of opium and

boric acid was applied and atropine instilled. Recovery was rapid and uninterrupted. Three months later, the eye was almost normal in appearance. The pupil was not quite circular. The vitreous was clear. Vision was 20/XXV +.

DR. F. BULLER, of Montreal, Canada, read a paper on "Foreign Body in the Retina." Six days after being struck in the left eye with a piece of metal, the patient, a man twenty years old, presented a penetrating wound of the cornea, with perforation of the iris and zonula, without opacity of the lens. A short distance below the papilla a piece of metal lay in the retina. Rest and instillation of a two-grain solution of atropine were ordered. A zone of opacity around the foreign body gradually increased in size. Twenty-six days after the injury, although the eye felt well and vision was 6/XII, there were pronounced evidences of neuro-retinitis. The piece of metal was still quite distinct. For a considerable distance around the foreign body there was marked atrophy of the choroidal pigment. Fourteen months later, the eye was still giving no trouble. Vision was $\frac{6}{27}$ +. There was diffused hyalitis, with fine opacities in the vitreous; the optic nerve was red and swollen; the foreign body, however, could no longer be seen. Its former seat was marked by a small patch of pigment.

DR. CHARLES STEDMAN BULL, of New York, reported a "Case of Traumatic Irido-Choroiditis from Contusion of the Eyeball, ending in the Development of Intra-ocular Glioma." The patient, a girl three years old, had been struck on the left eye by the bowl of a large spoon. There was no rupture of the eyeball. The child at once complained that she could not see. Ten days later, the eye was sightless; there was a central infiltration of the cornea, with loss of epithelium. The iris was dilated, discolored and immovable. The vitreous was hazy, and there was a yellowish reflex from the nasal portion of the fundus, due to an exudation. There was no pain or sensitiveness on pressure. One week later, numerous hemorrhages took place into the retina and vitreous, and the tension was increased. All external signs of irritation had subsided. Three months later, a detachment of the retina occurred, involving nearly two-thirds of the fundus. The yellowish reflex still remained and vessels were seen running over it. The tension still remained plus. Six weeks later, the sclera in the ciliary regions became thinned. Enucleation was urged, but refused. Four months later, the child was much worse. She was anemic and emaciated. There was a large ciliary and equatorial staphyloma; the anterior chamber was obliterated. The lens was opaque and crowded against the cornea, and the tension was much increased. The parents now, nearly a year after the injury, consented to an enucleation. The child at first improved much, but two months later she complained of headache and nausea, and the pre-auricular and submaxillary glands were found enlarged. Three weeks later, a growth was discovered in the orbit, and the upper cervical glands became enlarged. The symptoms grew steadily worse, and three months after the enucleation the right eye became involved, a small yellowish deposit being found in the inferior temporal quadrant. The left orbit became filled with the growth; the glands on the left side became enormously enlarged; the child became gradually stupid, then comatose, and died sixteen months after the blow on the left eye.

No autopsy could be obtained. A microscopic examination of the left eye showed gliomatous masses developed in a matrix of exudative tissue.

DR. G. E. DE SCHWEINITZ, of Philadelphia, read a paper on "Hyaline Bodies (Drusen) in the Nerve Head." He reported the case of a man forty-five years old, who had received an injury of the head some twenty years previously. The optic nerves were atrophic. The globular masses were arranged circularly slightly within the apparent margin of the head of the nerve. They were surmounted by shining particles that glistened like cholesterin crystals. After death, compound hyaline bodies or "drusen" were found in the head of the nerve, within the tissue of the papilla, anterior to the lamina cribrosa. The optic nerves were atrophic. The coats of the arterioles in the optic nerve below the lamina, and of the central artery in the neighborhood of the "drusen," were thickened. The optic nerve and the brain presented no abnormality.

DR. CHARLES A. OLIVER, of Philadelphia, reported Two Cases of Symmetrically-placed Opacities of the Cornea, occurring in mother and son. In both cases the condition had existed for a long time, and no cause could be ascertained.

DR. S. O. RICHEY, of Washington, read a paper entitled "The Prime Etiological Factor of Glaucoma is Constitutional." He traced a correspondence between an attack of podagra and one of acute inflammatory glaucoma. Many manifestations of rheumatic gout are associated with chronic glaucoma, viz.: enlarged or distorted joints, a peculiar, senile pallor, or muddiness of the skin, periods of mental depression, and other symptoms attributable only to changes in the nervous system. It was contended that chronic glaucoma is associated with neurotic manifestations that are to be ascribed to the absorption of toxic substances from the intestinal tract.

In the treatment of chronic glaucoma, the quantity and quality of food are to be carefully regulated in accordance with the physical needs; prompt excretion of improper intestinal products is to be favored; and uric acid solvents and strychnine and galvanism are to be employed.

DR. EDWARD JACKSON, Philadelphia, read a paper on "The Full Correction of Myopia." Of twenty-nine cases of myopia in which full correction was prescribed, in but three was there any notable increase in the degree of myopia, and these were hard students. The contra-indications are presbyopia and an exceptional inability to use strongly concave lenses for near work; lowered acuteness of vision, so that the perfect retinal images are not appreciated; habituation to large blurred images, which made sharper images unpleasant, as in old myopes; and divergent squint established to secure more perfect monocular vision.

DR. GEORGE C. HARLAN, Philadelphia, read a paper entitled "Constant Correction of High Myopia." He reported twelve cases in which full and constant correction of myopia of all degrees, varying from four to sixteen diopters, had been worn for periods of from five to seventeen years. The patients were from twelve to twenty-five years old. In some, the fundus was normal; in

some, there were moderate myopic crescents; and in others there were extensive choroidal changes. There was, however, not the slightest loss in the acuteness of vision in any case. In eight, the myopia was stationary; in three, there was a slight increase in myopia from 0.50 to 1.50 D.; in one only was there a considerable increase, 2.50 D., after constant correction for nine years. Excessive convergence without accommodation is the most important factor in progressive myopia. The restoration, so far as practicable, of the normal relation of these two functions is the most valuable therapeutic measure.

The degree of comfortable accommodation that exists, or can be acquired by practice with gradually increasing lenses, should be the chief guide in selecting the glasses to be used. The convergence will usually adapt itself when the accommodation is given its normal range; or if it does not, it may be made to conform by prisms or tenotomy. Complete correction of the optical defect, with full restoration of the normal relation between accommodation and convergence, is the ideal condition, and can usually be attained in young subjects with fair acuteness of vision and full accommodative power.

When full correction is impracticable it is better to sacrifice something in distant vision by the employment constantly of the strongest glasses with which comfortable reading is possible than to use two pairs of glasses.

Dr. Swan M. Burnett, of Washington, read a paper on the "General Form of the Human Cornea, and its Relation to Refraction of the Eye and Visual Acuteness." Measurements made with Javal's ophthalmometer demonstrate that the cornea gradually diminishes in curvature from the visual axis toward the periphery. This diminution is much greater to the nasal side. The difference in the vertical meridian is less than that to the nasal side, but on the average is greater than that to the temporal side. The practical inference is that the place of election in an iridectomy is the temporal side of the cornea. Dr. Burnett reaffirmed his belief that the ophthalmometer is one of the best means for making out astigmatism, but it cannot be relied upon to the exclusion of other methods, for it gives no indication of the degree of lenticular astigmatism, the existence of which the instrument itself has been mainly instrumental in demonstrating.

Dr. Swan M. Burnett, of Washington, further read a paper entitled "Some Incidental Phenomena of the Shadow Test." He maintained that the shadow test is an approximately reliable means of testing refraction. In a number of cases in which the findings of skiascopy and those of test-glasses did not coincide a play of shadows was observed within the illuminated area that moves across the pupillary space, similar to what is observed in conical cornea.

The phenomenon is ascribed to some interference with the regular refraction of the light in its outward passage from the fundus, and must be found in the corneal substance (not sufficient to produce a discoverable opacity), or in the surface or substance of the lens. In all cases in which the internal shadows were at all pronounced the visual acuteness was below the normal. In some instances, the shadow-tests give reverse movements with minus glasses, when plus glasses were required to improve vision, the examination being made under a mydriatic.

Dr. Herman Knapp, of New York, read a paper entitled "The Law of Symmetry of Our Eyes, as Manifested in the Direction of their Meridians: its Rules and its Exceptions." He considered the symmetry of one eye as a whole as compared with its fellow with regard to the median line of the body. In 1000 successive cases of astigmatism it was found that the meridian of strongest refraction (shortest radius of curvature) was symmetrically placed in 84 per cent.

The dominating direction is the vertical (60 per cent.); next comes the horizontal (11 per cent.); then the diagonal with 4.3 per cent.

Dr. Knapp proposed a classification of the varieties of astigmatism based on the direction of the strongest meridian, viz., vertical, horizontal, and intermediate or oblique astigmatism. A deflection of 45° may be called diagonal. The oblique variety has to be subdivided into nasal oblique (or simply nasal), and temporal oblique (or simply temporal).

Dr. George C. Harlan, of Philadelphia, read a paper, giving "Statistics of Direction of the Principal Meridians of the Eye," the results obtained being similar to those presented by Dr. Knapp.

Dr. Charles A. Oliver, of Philadelphia, read a paper on "The Clinical Value of Repeated Careful Correction of Manifest Refractive Error in Plastic Iritis," as a result of a study of forty cases.

In nearly every case of iritis, especially if plastic, there is a period, even after full pupillary dilatation has been seemingly artificially obtained, during which, owing to the persistence of inflammatory changes in the uveal tract, graduated instillations of mydriatics should be employed; the duration and gravity of this period is most accurately measured and determined by the systematic and repeated estimation of the varying manifest errors of refraction.

Whilst, during this stage, there are at times curious changes of corneal curvature, the bulk of the ametropic change is due to the perversion of the lens's action from what is termed "spastic accommodation," as the result of ciliary irritation and inflammation.

In nearly every case of iritis the duration of this stage can be promptly shortened by the judicious and ready use of some quick and powerful intra-ocular muscular paralyzant.

In some few such cases, however, during the acme of the attacks, especially if the case be pronounced in type and stubborn in character, the higher grades of refractive error seem to obstinately persist with but little variation, and to defy local and general measures.

In some cases of incipient iritis in which clonic spasm of the ciliary muscle is present, or pupillary contraction persists, local muscle paralysis is often quickly obtainable by a prompt and more energetic employment of powerful and appropriate local and general remedies.

Dr. Oren D. Pomeroy, of New York, read a paper entitled "Some Tenotomies of Recti Muscles for Insufficiency," reporting four cures in which the operation had been performed. Most of the cases of insufficiency had been relieved by correcting the ametropia.

In dividing the tendon, in some instances, an aperture

has been made in the center and a small hook passed in, dividing successively each half. This is a difficult procedure, and is not necessary. Ordinarily the conjunctiva is dissected as little as possible, and the tendon is divided at its insertion; the patient is then tested by prisms, and if the result is not satisfactory more dissecting is done. It is difficult to determine by inspection whether or not all of the tendon has been divided. A little over-effect is usually desired, and if considerable over-effect is obtained a suture will correct it.

DR. H. F. HANSELL, of Philadelphia, read a paper on "Prominent Symptoms of Hyperphoria," based on a study of thirteen cases. In two cases, the symptoms were purely local. Photophobia of moderate degree was present in five cases. Pain in the eyeball, constant, or induced by reading, was prominent in all cases.

Six cases suffered with vertigo. In two cases, marked dyspepsia was present. In four cases, the most prominent symptoms were nervousness, irritability of temper, and at times mental confusion.

SECOND DAY—JULY 21ST.

DR. CHARLES STEDMAN BULL, of New York, presented "A Contribution to the Subject of Intra-cranial Lesions, with Defects in the Visual Fields; Five Cases, with Autopsies." The first case was that of a woman, fifty years old, who had received a severe mental shock, followed by convulsious and profound nervous prostration. Then followed severe neuralgia, recurring every three weeks and lasting for more than a year. The first ocular symptom was night-blindness in one eye, with progressive amblyopia. A year later, the other eye became affected in the same way. Headache then came on, boring in character and located at the vertex, but subsequently becoming continuous and confined to the occipital region. In the left eye there was a large irregular central scotoma for form and color, and in the right eye a smaller scotoma. The fundus of the right eye was but little affected, but the left eye presented a declining neuro-retinitis and beginning atrophy of the optic nerve. The patient lived four years, with steadily failing vision. During the last year, she had repeated attacks of unilateral convulsions, became wildly delirious, and died in a violent general convulsion. The autopsy showed extensive pachymeningitis of the convexity of the left anterior lobe, some patches over the right anterior lobe and one large patch over the right parietal lobe. All the arteries at the base of the brain were thickened and their lumen narrowed.

The second case was in a young man aged twenty-four years, who had suffered from headache for more than a year, at first slight and transient, but increasing in severity and intensity. Six months later, muscular twitchings appeared in the upper extremities and face, with attacks of vertigo. The vision of both eyes became affected. In a paroxysm of general convulsions, the patient fell a distance of thirty feet, striking on his back, but without apparent evil result. There was concentric narrowing of the field of both eyes, which steadily increased; vision slowly failed. The optic discs, which were at first hyperemic, became pale and atrophied. About six months after the first convulsion, the man had two violent convulsions in rapid succession, which proved to be the last. He became irritable, grew stupid, and gradually sank into profound coma, in which he died. The autopsy revealed a large tumor involving the optic chiasm, both optic nerves and the hypophysis, which on examination proved to be a small-cell sarcoma.

The third case was in a man thirty-seven years old, who had suffered from severe headache in the left parietal and occipital regions for about nine months. Two months later, loss of vision in the right half of each field was detected. Six weeks before coming under observation, the sense of smell was suddenly lost. Examination showed vision in each eye to be 20/L and disclosed a bilateral right hemianopsia, with concentric limitation of the remaining fields. The man had had a chancre twelve years before. The intra-cranial lesion was believed to be a gumma and was located in the cuneus. In spite of treatment, there was a steady failure of vision, and muscular twitchings in the face and hands appeared. The man gradually became stupid, then comatose, and finally died, fourteen months after the first appearance of the headache. At the autopsy, an olive-shaped tumor was found in the cuneus on the left side, close to the median line. The growth proved to be a small-cell sarcoma.

The fourth case was in a woman seventy-two years old, who had suffered with headache for more than a year. Six months before coming under observation, she awoke with severe pain in the head and total blindness in the left eye. There were confusion of ideas, numbness of the right arm and leg, and thickness of speech. There was slight ptosis of both upper lids; speech was thick and slow; the tongue deviated to the right side; vision was 20/XL; there were slight lenticular opacities and bilateral left hemianopsia. The ophthalmoscopic examination was negative. It was thought probable that there had been a thrombosis followed by rupture of the middle cerebral artery on the left side. The woman lived for twenty months, vision failing, but the fields remaining unchanged. One morning she was found unconscious, and died three days later. The autopsy showed a patch of softening in the left anterior lobe; in a branch of the middle cerebral artery running through it was an old plug completely obliterating the lumen of the vessel. There was a recent rupture of a branch of the left middle cerebral artery and a large clot of blood in the middle lobe of the brain close to the Sylvian fissure. All of the arteries of the brain were diseased. At the base of the brain on the right side, overlying and pressing upon the right optic tract, was a tumor as large as a hazel-nut, situated just in front of the corpus geniculatum laterale. This proved to be a small-cell sarcoma.

The fifth case was in a man thirty-five years old, who for three years had suffered from severe headache, beginning in the frontal region, but gradually extending all over the head; at first intermittent, but later constant. There were occasional attacks of nausea and vertigo. Four years previously he had received a violent blow in the left parietal region, followed by bleeding from the left ear and rapidly increasing deafness. For nine months there had been diplopia, and for six weeks partial left heminesthesia. There was paresis of both external recti muscles. Vision in the right eye was 20/C; in the left eye 20/L. There was marked papillitis, with numerous hemorrhages. There were homonymous di-

plopia for all distances; irregular central scotoma for all colors; marked vertigo, with a tendency to rotate to the right side. A diagnosis of cerebellar tumor was made. Toward the close of life the man became nearly blind; he died in profound coma. The autopsy revealed a globular tumor in the right lobe of the cerebellum close to the peduncle. The growth proved to be a glio-sarcoma.

Dr. Charles W. Kollock, of Charleston, S. C., read a paper on "Monocular Amblyopia in the Same Family," reporting four cases cf amblyopia in members of the same family—two brothers and two sisters. In all the left side was affected.

Dr. Kollock also read a paper on "The Eye of the Negro." Many of the eye affections observed in negroes were traceable to syphilis and to the changed conditions in their life since the war. Ulcerative keratitis is quite common among the negroes, but trachoma is exceedingly rare. Cataract is equally frequent in the negro and white. Glaucoma is of equal frequency. Retinitis, optic neuritis, and choroiditis are not infrequent. Retinitis pigmentosa had not been observed in the negro. No case of embolism of the cerebral artery had been observed. Xerosis of the conjunctiva had been seen in one case in an adult. Orbital tumors seem uncommon in negroes. Two cases of abscess of the orbit had been seen in negro children.

Myopia was not common in pure-blooded negroes before the war, and is still rare. Three cases of myopia had been observed in the pure black. Comparatively few pure bloods have been examined for refractive error.

Dr. W. F. Mittendorf, of New York, read a paper on "The Frequency of Posterior Capsular Opacities at the Place of Attachment of the Hyaloid Artery." He called attention to the frequency of small round lenticular opacities, believed to be the remains of the fetal hyaline artery, or to mark the attachment of the artery to the posterior lens capsule. Of 1884 persons, these opacities were observed in 44 cases, a little more than 2 per cent.; they were observed more frequently in the right eye than in the left, and oftener in the male than in the female; not infrequently they were seen in both eyes. They vary in size from a dot as small as the point of a pin to one as large as a poppy seed; frequently a magnifying power of a lens of five or six diopters is necessary to see them.

Dr. Oren D. Pomeroy, of New York, presented a paper on "Some Cataract Extractions with and without Iridectomy," which was read by title.

Dr. Carl Koller, of New York, exhibited "Preparations of the Nerves of the Cornea." The peripheral nerves were stained by Ehrlich's method by the injection of a saturated solution of methylene blue into the vessels of a recently-killed animal. The nerves of the cornea are colored in a beautiful manner, but the stain is only temporary, and does not permit of the making of preparations.

Dr. T. Y. Sutphen, of Newark, N. J., read a paper on "Scleral Puncture in Detachment of the Retina." He reported two cases of detachment of the retina in which the sclera was punctured. In the first, useful vision was restored; in the second, the improvement was but slight.

Dr. E. E. Holt, of Portland, Me., reported "A Case of Orbital Cellulitis," in which the inflammation spread to the temporal region, thence to the neck, interfering with deglutition, and to the brain, producing death. Four other simliar cases were referred to.

Dr. Charles J. Kipp, of Newark, reported "A Case of Recurrent Bilateral Inflammation of the Capsule of Tenon, in Connection with Mercurial Poisoning." The first attack followed an injury, but was succeeded by repeated attacks. The patient was employed in an incandescent electric lamp manufactory and had become poisoned by the mercury used in his work. The recurrences continued until he gave up this work. There has been no attack since a year and a half.

Dr. R. A. Reeve, of Toronto, Canada, read a paper on "Pulsating Exophthalmos." He reported a case in which pulsating exophthalmos followed a trauma. It was thought that there was a lesion of the internal carotid, allowing the blood to enter the cavernous sinus. Pressure upon the carotid failed to control the pulsation. A year ago, the right common carotid was tied. Pulsation and bruit ceased for a few hours and then returned. Some months later, finding that compression of the left common carotid controlled the pulsation and bruit, this vessel was tied, but the pulsation still persists. There is pulsation in the right carotid above the seat of ligation. Pressure upon the right external carotid stops the pulsation and bruit absolutely.

Dr. Carl Koller, of New York, read a paper entitled "Sub-conjunctival Application of Cocaine." He stated that by injecting a few drops of a 1 per cent. solution of cocaine beneath the conjunctiva, after the application of a 4 per cent. solution to the surface, tenotomy, cataract operations, and iridectomies can be performed without the slightest pain.

Dr. Koller also read a paper on "The Form of Retinal Images in Astigmatic Eyes."

Dr. Charles J. Kipp, of Newark, N. J., reported "A Case of Gumma of the Ciliary Body," and exhibited the specimen.

Dr. F. Buller, of Montreal, Canada, exhibited "An Improved Trial Frame."

Dr. J. A. Andrews, of New York, showed an "Apparatus for Washing Out Cortical Matter." He also exhibited drawings of "Four Cases of Gumma of the Iris."

Dr. Lucien Howe, of Buffalo, demonstrated "A Pocket Ophthalmoscope."

Dr. R. A. Reeve, of Toronta, described "A Modification of the Rotary Prism Test."

Dr. John Green, of St. Louis, reported "A Case of Hyaline Bodies in the Nerve Head."

The following officers were elected:

President.—Dr. Hasket Derby, of Boston.

Vice-President.—Dr. George C. Harlan, of Philadelphia.

Corresponding Secretary.—Dr. J. S. Prout, of Brooklyn.

Recording Secretary.—Dr. Samuel B. St. John, of Hartford.

Delegate to the Executive Committee of the Congress of American Physicians and Surgeons.—Dr. John Green, of St. Louis.

Alternate.—Dr. D. B. St. John Roosa.

The following were elected to membership:

Dr. J. A. White, of Richmond, Va.; Dr. Walter B. Johnson, of Paterson, N. J.; Dr. G. W. Hale, of Nash-

ville, Tenn.; and Dr. R. L. Randolph, of Baltimore, Maryland.

The next meeting will be held at New London, Conn., on the third Wednesday of July, 1893.

BRITISH MEDICAL ASSOCIATION.

Sixtieth Annual Meeting, held at Nottingham, July 26, 27, 28, 29, 1892.

FIRST DAY—JULY 26TH.

MR. JOSEPH WHITE, of Nottingham, delivered the President's Address, reviewing the development of the work of the British Medical Association and of British Medicine and Surgery since the last Nottingham meeting. He extended a hearty welcome to the participants in the meeting, and made reference to the geologic and sanitary conditions of Nottingham.

The British Medical Association last met at Nottingham in 1857. The meeting was a small one, as compared with the magnitude of the present congress. Some eighty or ninety members were present.

Credit was given to Sir Charles Hastings, the founder of the Association, for his assiduous zeal and labor, and his enlightened and enthusiastic efforts.

The original objects and aspirations of the Association were the collection of important medical and surgical knowledge arising from public and private practice in the great provincial centers and in rural districts; increase of knowledge of the medical topography of England, in its widest sense, and which could best be collected by those resident on the spot; investigations of the modifications of endemic and epidemic diseases in different situations and at various periods, so as to trace their connection with peculiarities of soil and climate, or with the localities, habits, and occupations of the people; and, perhaps, most important of all, the maintenance of the honor and dignity of the profession generally by promoting friendly intercourse and free communication amongst its members, and by establishing between them that harmony and good feeling which ought ever to characterize a liberal profession.

When the Association last met at Nottingham the number of members (and this represented a quarter of a century of successful work) was 2065; now it is more than 14,000. Then all the meetings were held in one small room, on the low pavement known as the Assembly Room; now the whole of the magnificent suite of rooms which the authorities of the town and the Council of the University College have most kindly and liberally placed at the disposal of the Association is required, and even these are not large enough for general meetings. Then the branches were confined within the limits of the southern half of Great Britain; now they extend to most of the British possessions throughout the world. In North and South America, in India and China, in Burmah, in the West Indies, and in the islands of the Mediterranean, at the Cape, and in Australia, there are numerous and increasing branches, and year by year an ever-increasing number of professional brethren are feeling the power and adding to the influence of the Association. But not only has the Association increased numerically and in the extension of its area, but it has increased in a still greater ratio in the character and importance of its work.

The address continued with an interesting historical and critical summary of the more important work that been done in the various departments of medicine in the last forty years.

SECTION OF MEDICINE.

The PRESIDENT, DR. W. H. RANSOM, of Nottingham, delivered an address on "Some Diseases of Plants Compared with Those of Man." The paper was based on a long though desultory study of diseases of plants, seen from the point of view of the student of medicine.

Inflammation in plants was defined as the reaction of living cells to irritation. All such reactions in plants produce what are, or may be, called galls, using the word widely, but some of them which occur in growing points are known as witch-knots. It may be convenient to add that a gall should be considered as a local hyperplasia, or overgrowth of tissue, which differs from a local hypertrophy in that it diverges in structure and form from the normal tissue or organ with which it is related, and injures, or at least does not benefit, the plant. The causes of such reactions, or in other words the irritants, may sometimes be mechanical or physical agents, or inorganic chemical substances, but as a matter of fact all those which have been most successfully investigated inhere in living organisms. These organisms are very diverse, so that nearly every order of insects presents us with some examples. Among the acari the Phytopi, or gall mites, are the best known; some anguillulæ have long been known to produce galls, and some parasitic fungi, as well as certain as yet imperfectly classified organisms, also cause galls.

Numerous examples were given to show some of the grounds upon which is founded the hypothesis that the irritant is an organic chemical substance, and also to support the view that the process of irritation is some gentle, persisting disturbance of the metabolism of the living cells, during which cell-multiplication is inhibited where it first acts, but stimulated just outside that part. Such disturbance is propagated in some unknown way through the gall-tissue, so as to act differently at different distances in different directions, and may extend to tissues outside the true gall, and varies at different stages of the evolution of the gall.

The process of reaction, which is necessarily conceived of simultaneously with that of irritation, has its source in that fundamental faculty of repair and reproduction which plants, in common with all organisms, necessarily possess. The power of reaction to irritation resides in all the living cells, although most marked in the younger, as is also true of the processes of repair and of reproduction. The process itself may be conceived of as a compensative cell-proliferation directed and modified in its character by the irritant, so that the result is at once heterologous and specific.

When a part of a living plant is injured, it dies if the damage be serious, and the nearest living cells multiply, so that in wounds of parenchyma one and the same kind of tissue, known as cork, always results, whatever may have caused the injury, and in wounds which involve the great cambium, repair is effected by another tissue, known as callus, which is always the same whatever may have produced the injury. Repair, then, is not specific in relation to the cause of the injury, but in similar tissues is always the same. Both cork, which is the scar-

tissue of plants for injuries of parenchyma, and callus, which is the same for wounds of axes, are normal and permanent plant-tissues, and the latter has within itself all the potentialities of the whole plant, being able to reproduce roots and shoots. The whole process of repair is a physiologic one, that of reaction to irritation a pathologic one, and it is only when the two processes are mixed that confusion can arise.

As all the reactions to true irritation are by the hypothesis inflammations in plants, this expression includes both those well-defined galls of complex structure and somewhat independent life which are usually called tumors of plants, and those more variable and indefinite local hyperplasiæ due to irritation, which are often so slight as to escape attention, and would more naturally be spoken of as inflammation. In all, however, the irritant directs the reaction and the product is specific. Malformations, such as witch-knots, etc., probably belong to the same category; they differ from galls mainly in that the reaction which produces them results from the irritation of a developing germ, and that it produces rather an abnormal arrangement of otherwise normal organs than a true local hyperplasia.

As morbid processes in plants belong to the domain of general pathology, they may properly be considered in relation with the corresponding processes in animals.

The following general theory of inflammation was proposed:

In virtue of those necessary and inherent faculties by which all organisms repair damage, living cells react in response to true irritations by a proliferation with modification directed by the irritant, and not beneficial to the organisms in which the process occurs.

According to this view, all inflammations are specific, From the purely clinical standpoint many inflammations would still be spoken of as simple or common, but with the progress of etiologic knowledge the number of specific inflammations would increase at the expense of those which from lack of etiologic knowledge only are called common.[1]

The arguments used in reference to inflammation admit of application to fever, although the equivalent of that process is not yet recognized in plants; but remembering how many fevers are now known to be specific, their intimate connection with inflammations, and the specific effects of poisons and drugs both upon the organism as a whole, and upon the several organs and tissues, such an extension of the doctrine, which is indeed apparently a necessary corollary from the truism that causes are factors which must always effect the results in some degree, would have some basis of support.

The greater complexity of structure and function in the higher animals than in plants, and especially the more immediate dependence in the former of every tissue and organ upon the integrity of the nervous and circulatory system, sufficiently account for those differences in the inflammatory process which are known to exist.

Section of Surgery.

The President, Mr. John Croft, of London, opened the session with an address in which he briefly adverted to the three topics selected for discussion. He made the following propositions relative to the surgical treatment of pleural effusions, serous or puriform: 1. Early evacuation is the best principle to act upon. 2. The exclusion of air when practicable and the observance of aseptic or antiseptic *technique* should be rigidly observed. 3. Complete and perfect drainage of the cavity under treatment is essential, including counter-openings and large openings into the pleura or other pus-holding cavities. 4. Large cavities require adequately large openings. 5. Ribs and periosteum, intercostal vessels and nerves may be largely excised with advantage immediate and prospective, so long as ordinary precautions are observed. 6. Lack of early and adequate operations is an important, though not the exclusive cause of delay in the closing of cavities. 7. Lung-abscesses and gangrene and bronchiectatic cavities, with certain obvious exceptions, are amenable to surgical exploration and treatment. 8. Hydatid cysts in the lung or pleura may be successfully extracted or otherways cured by thoracotomy.

When an enormous pleural cavity is bounded on one side by a collapsed, movable, swinging, dangling lung, and on the other side by rigid bony wall, the difficulty is a formidable one, particularly when there is little or no disposition to the formation of granulation or cicatricial tissue. Sponge-grafting has failed. Abstraction from the wall of the chest of a great portion of its bony rigidity does not necessarily succeed.

In this connection the question arises, Would the removal of the useless swinging lung, at or near its root, be a safe and useful measure? Its presence is an obstacle to the cessation of discharge from the pleura, and its removal would be a step half-way to cure, if adequate measures for its fixation have failed of their purpose.

Tuberculous cavities associated with other tuberculous deposits and multiple bronchiectatic cavities have as yet proved insurmountable diseases and difficulties.

Since the introduction of antiseptics and aseptic modes of operating, a decided improvement has taken place in dealing with the pericardium and its troubles. It does not present the same conditions for difficulties and such exceptional states as the lungs and pleuræ.

Brilliant as are the results obtained in the surgery of the liver and gall-bladder, there remain difficulties yet to be overcome and questions yet to be settled. Among these are: 1. The treatment of hydatid cysts of the liver which have already opened or which threaten to open into the chest. 2. The question of early operation in cases of cholelithiasis. 3. The desirability of suturing the incision into the gall-bladder and of then closing the abdominal incision and cavity. 4. When the gall-stone is impacted in the duct and cannot be reached through the gall-bladder, should the duct be incised and the incision sutured, the omentum being employed to strengthen the fastening? 5. The question of whether ligature of the cystic duct without cholecystectomy is to be preferred to other operations. 6. The cases in which cholecystectomy is to be preferred to less radical procedures. Lastly, the interesting topic of cholecystenterostomy will arise—when it is to be resorted to and the best mode of carrying out the operation.

The subject of the surgical treatment of tuberculous disease is still one of the burning questions of the day.

[1] By this theory in animals, as well as in plants, all tumors due to a reaction to irritation would be included in the term inflammation, as probably also would be some of the malformations.

In spinal diseases we have a study of tuberculous disease of bones and joints. The essential pathology of disease is the same whether the neoplasm is in bones or joints of limited mobility—as in the spine—or in the bones or joints of the utmost mobility in the extremities.

In discussing the treatment of tuberculous abscesses connected with disease of the bones and joints of the spine, the vexing questions as to shortening of the limbs, arrest of growth from excision of epiphyses, flail-like joints after operation, acute infective tuberculosis after excisions, do not, or should not, embarrass the discussion. No one, as far as known, has yet attempted cure by excising the vertebral column with the joints.

There are at least two most remarkable lines of practice that widely differ from the old modes of treatment: The cure of tuberculous spinal abscesses, without septic sinuses, by repeated aspirations and iodoform-injections, no larger operations than those being performed; and the cure of the same condition of large abscesses by free incision, evacuation of all cheesy deposits and sequestra, obliteration of the lining tuberculous membrane without the permanent introduction of an antiseptic, and these proceedings followed by complete closure of the wound without draining.

SECTION OF PSYCHOLOGY.

The President, DR. W. BEVAN LEWIS, L.R.C.P. Lond., of Wakefield, delivered an address "On Some Desirable Extensions of Asylum Administration." He dwelt upon the importance and the necessity of having a competent pathologist in the service of every insane asylum. To facilitate the training of men in institutions that have no regular pathologist, leave of absence for a varying period should be granted to house-officers for the purpose of special tuition. By the establishment of out-patient departments in connection with insane asylum cases may be secured in the earliest stages of mental disease. Courses of lectures on nursing and ambulance service constitute a most commendable feature. Out-door private nursing may be provided by choosing a certain number of skilled nurses as a private nursing staff, temporarily resigning their positions on the staff, their wages and incidental expenses being paid out of a fund accruing from their earnings. The vacancies on the staff thus created are filled by probationers, who offer their services unpaid for instruction in nursing and who succeed to the vacancies occurring from time to time from resignation and other causes.

SECTION OF PATHOLOGY.

The PRESIDENT, MR. VICTOR HORSLEY, of London, made some introductory remarks. He stated that pathology, as such, is almost unknown. What is commonly spoken of as "pathology," taught as "pathology," and made the subject of examinations in "pathology," is not pathology, but morbid anatomy.

The pathologist should be the student of disordered function as well as of disarranged structure; morbid anatomy is, therefore, but one side of his work; pathology is the other. What is required at the present day is the accurate determination of the aberrations of normal function, and, judging by the strides normal physiology as a science has made, no difficulty attends the pathologist in this new and fertile field. A mass of facts has been accumulated in elucidation of the various changes in the structure of the lungs produced by pneumonia, phthisis, etc.; but how many workers have been found to investigate the degree and effect of the loss of the respiratory function, of the disorder of the normal oxygen and carbonic acid ratios? Yet this is it that kills; this is the whole work of the disease, and this is what must be solved before the treatment of such diseases can be worthy of mention other than as mere empirical palliation. This, the pathology of the diseases of the respiratory organs, is a subject before which the facts of morbid anatomy will seem more and more restricted as the intricacy and breadth of the problems it is often supposed to solve are properly considered and appreciated.

Another example—a much smaller one, but involving most fundamental considerations—is the condition spoken of as edema or dropsy. What is more common at the present day than to hear this condition gravely ascribed to alterations in the blood-pressure alone, and chiefly to venous stagnation? Yet this view has for more than twenty years been absolutely contradicted by experimental pathologists, and shown to be untenable. This surprising indifference to pathology is due to want of familiarity with modern progress in physiologic and chemical research. Fortunately, laboratories are springing up now on all sides, original investigations are being pushed forward, light and knowledge widely diffused. The reproach that we have been dead-house students rather than true pathologists will, therefore, soon be wiped away.

SECTION OF DISEASES OF CHILDREN.

The President, DR. LEWIS W. MARSHALL, of Nottingham, delivered an address on "The Need for Systematic Instruction in Diseases of Children." He deplored the lack of practical instruction in the recognition and management of the diseases of children. To this deficiency are to be ascribed many of the false traditions that remain, and not a few of the ills from which children suffer.

SECTION OF PHARMACOLOGY AND THERAPEUTICS.

The President, DR. J. O. BROOKHOUSE, of Nottingham, delivered an address on "Some Points in Pharmacology and Modern Therapeutics." Medicine, in its largest and broadest significance, is at once an art and a science, and is based upon observation, experiment, and practice. As a science it must necessarily be inexact, for it deals with the highest organism—that of man—under conditions the most uncertain, unstable, and complex. Hence the apparent fallacies in experiment, the errors in observation, and the slow and uncertain advance in practice. In purely and simply experimental research and laboratory work, at least some of the ordinary sources of fallacy may be controlled or eliminated, and thus more definite and correct conclusions be arrived at. To few, however, are such opportunities afforded, and with the rank and file of the profession rests not merely the recognition of disease and its treatment, but to no inconsiderable extent the advance of medicine in its practical issues.

If, however, it cannot be claimed that experimentally very large additions have in recent years been made to our powers of cure, in two directions at least there have

been originated methods of procedure which have already added somewhat to these powers, and which are of great promise for the future. Most of our present remedies are the outcome of experiments made on natural products, animal, vegetable, or mineral, or on compounds which the chemist has put at our disposal in his efforts to penetrate those secrets of nature with which he is specially concerned.

Chemistry has taught us that the various organic groups may be combined in an almost infinite variety of ways, and that it is possible thus to produce thousands of new bodies, each of which will have a special action on the tissues and organs according to the groups of which they are composed, and the method by which the groups are united. Of late the chemist and the pharmacologist, working together, have built up for medicinal use a large number of these new compounds, joining together organic groups for definite purposes.

At least a score of new substances have been introduced during the past twelve months for the purpose of fulfilling some definite therapeutic want, and though doubtless many, probably the majority, will not be of practical service, still there is evidence that some may prove to be very useful medicinal agents, and there is great hope that with increasing knowledge new compounds will be formed which will be of incalculable value in the treatment of disease.

The second therapeutic departure to be noted is for the most part one of promise only. It comprises the use of the products of the lower forms of life which are connected with disease, or, again, of the use even of microbes themselves as therapeutic agents.

The question whether the experiments made on the lower animals will enable us eventually to deal effectively with infectious diseases in man is one of great interest and importance.

It is quite possible that some methods of treatment, founded on the knowledge which has been gained by the influence of microörganisms and toxines, may not prove capable of practical application; if, however, this be the case, certain facts as to this influence are proved, and we have good grounds for hoping that further experiments made on the use of microörganisms and their products will before long put in our hands new therapeutic agencies for the cure of infectious diseases in man.

Any reference to modern therapeutics would be incomplete without a passing glance at modern diseases. One cannot be unobservant of the vast proportionate increase during the past twenty years of diseases of the nervous system. The business and social conditions of daily life are vastly altered. We live at high pressure. Competition, rapidity of travel, ambition, the struggle for wealth, place, and power, with all the anxieties, cares, and worries involved therein, the exactions of social life, what is spoken of as "hurry," and a thousand and one other such things, have undoubtedly been productive of serious functional nerve-disturbances previously unknown, whilst others involving coarse lesions have been rendered more common. Further, long-continued functional disturbance alone may, and not infrequently does, bring about organic change, such change being the outcome of perverted and impaired nutrition.

In these conditions of physical strain and mental tension we have a state provocative of nerve-changes both coarse and subtle, but all degenerative in type. With these, therapeutics has not, and cannot, keep pace. The requirement of the sufferer is for speedy, nay immediate, relief; but the call is in vain. We now, no more than formerly, have the power to build up new and healthier tissue. The human machine refuses to acknowledge any law other than the law of nature, and there is no therapeutics outside the universality of her harmonies.

Seven cases of pulmonary tuberculosis, at various stages, were reported satisfactorily treated by intra-tracheal injections of menthol.

The method consists in the introduction once or twice daily into the trachea of one dram of a 12 per cent. solution of pure menthol in pure olive oil; this is effected by the aid of the laryngoscope, and a syringe specially made with a curved tube; the tube is passed through the rima glottidis, about half an inch down the trachea. After a little practice and habituation, the patient feels no inconvenience or discomfort whatever; on the contrary, there arises an agreeable sense of warmth in the chest. An early result is a marked diminution of the cough and expectoration; the night-sweats, if previously existant, cease; the hectic temperatures become less marked, the curves become normal, and the patients gain in weight.

Despite therapeutic and pharmacologic advances; despite new remedies and new methods of cure, the tendency, in increasing measure, of modern thought and practice is toward the recognition and employment of preventive as distinguished from curative medicine. A larger and better understanding and observance of the laws of health, a more perfect knowledge of the causes and spread of disease, the attainment of a higher educational and intellectual standard, have in part contributed to this. May not also the thought of the inadequacy of curative medicine in grappling with disease constrain us to endeavor rather to anticipate those conditions which appear to underlie and give rise to morbid change? And in matters of personal health this question dominates the entire position. It is unquestionably easier, for instance, to employ measures to maintain the standard of health, even in those, for example, phthisically disposed, than it is to arrest the disease when once in activity.

Second Day—July 27th.

Address in Medicine.

Dr. James Cuming, of Belfast, delivered the Address in Medicine. He considered the position of medical science in the general world of thought and its relations to certain other branches of knowledge with which it is allied.

In view of the extent to which certain of the natural and experimental sciences, namely, chemistry, botany, and physics, have grown, the question arises as to restricting the limits within which these should be taught the medical student. Would not the principles of chemical science suffice amply for his practical wants, which after all are comparatively simple? When the practitioner of medicine has tested for albumin and sugar, and is familiar with the composition and reaction of a few urinary deposits, and knows that a condition of acidity may be temporarily relieved by an alkali, he has pretty completely gained all the information of practical

value which chemistry is likely to give him for the needs of his daily work. The tests for the principal poisons and alkaloids may, perhaps, be added.

As regards botany, does the botanic source of our remedies in any way elucidate or guide us in their application, or would the majority of us recognize the plant in its growing or dried form from which we derive our most valued agents?

As for natural philosophy, everyone will admit that any considerable, not to say profound, knowledge of subjects which have received so much attention at the hands of physicists, and which have been worked out with such minuteness and care, and of which the full comprehension entails so much mathematical acquirement, are altogether beyond what may be fairly required from a student of medicine.

It may be urged that the study of the ancillary sciences, as they have sometimes been called, is of high importance to the discipline of the intellect, and tends to develop the habit and the power of careful and accurate observation; and this may be admitted in the fullest and most ungrudging manner. But the powers of the average human intellect are far from illimitable, the capacity of attention is bounded, and the sum of mental energy requires to be carefully husbanded, to be directed in the right channels and not to be allowed or compelled to dissipate in useless effort.

Our anatomy must be thorough, though not unnecessarily minute and elaborate. It should be learned so that the body will be, as it were, transparent to the eye. Then we can afford to dispense with no considerable portion of the wide and fruitful field of physiology, a science which is now so extended and so rapidly increasing that many men of science are specializing themselves on different portions of its vast territory.

Among the subjects of greatest present interest there are two that seem to give evidence of distinct currents of thought moving apparently in opposite directions. On the one hand, we find an important part in pathologic and physiologic processes ascribed to minute organisms, the white corpuscles or leukocytes, which are apparently free from all direct nervous influence and float freely in the blood; and, on the other hand, we find that the domain of the most highly organized and differentiated part of the body, the nervous system, is being extended and increased.

A new cellular pathology is being developed, differing widely indeed from the brilliant theory bearing this name, so long familiar to us from the powerful advocacy of Virchow; but agreeing with it in the important functions assigned to the ultimate elements of the body as independent factors, both in morbid and in healthy processes; and also in representing them as being either uninfluenced or as only indirectly influenced by the nervous and vascular systems in some of their essential activities.

The study of medical psychology alone is a very incomplete and inadequate preparation for comprehending the multiform disturbances of mental function, and is even more inadequate in respect of either diagnosis or therapeutics, and in regard to the expectation of adding to our knowledge of cerebral diseases, as regards either localization or character.

Some knowledge of psychology proper, that is of the science of the phenomena of mind in its normal conditions, is absolutely necessary. Without an acquaintance with the problems and methods of psychologic inquiry it is impossible to observe and to describe adequately the phenomena of morbid mental states. In the investigation, also, of those conditions in which the disturbance of a single function is what is most manifest and striking, it is clear that a knowledge of the limits and differentiation of function must be of capital importance. It will be of value also to become familiar with the terms used in psychology, in itself a study of no inconsiderable difficulty and extent. In dealing with such questions as amnesia, aphasia, delusions and hallucinations, and other disturbances of consciousness we are not only in the sphere of our legitimate activity and of our daily work, but we are touching, not indirectly, on some of the most interesting problems of mind.

We need not attempt the great metaphysical questions of substance, reality, the nature of consciousness, the ontologic nature of space and time, the essence of causal action, and the like. The domain of the clinical and pathologic observer is an humbler but a more fruitful one. Just as biology concerns itself with the manifestations of life and puts aside all theories regarding its nature and origin, just as in fact all sciences have to resolutely set aside at the beginning a certain number of unsolved questions, so we may fairly relegate these problems to other and more competent authority.

Nor is much to be gained at present by attempting to form any wide generalizations. A working hypothesis is, no doubt, of the highest utility in an experimental science, even if it ultimately comes to need to be corrected or to be altogether abandoned; and if the facts that come before us were capable of being called into existence, or of being modified at pleasure, such an hypothesis might be necessary for our guidance. But we have to deal only with phenomena not susceptible of voluntary modification, and what we have to do is simply to observe them with accuracy and to record them with fidelity. In these observations the materialist who regards mind as a form of motion in the brain-cells, and the spiritualist who looks on it as an immaterial principle underlying the phenomena of consciousness, although acting through the nervous system, can work together in perfect harmony, as the problem is to observe and analyze the phenomena brought before them. Even in this task there are limits set to our observations that it is not easy to surmount or evade.

One of the definite lines on which medical observation might be of the greatest value in elucidating some unsettled problems is furnished by the aberrations and decay of memory. For this species of observation no apparatus is necessary, and the opportunities are daily offering themselves, and most abundantly, to the busiest practitioner.

Nor even in a therapeutic sense will studies of this kind fail to bear fruit in enabling us to deal more rationally and more successfully with the morbid conditions of this important portion of the economy. It can hardly be denied that there is a tendency among the most enlightened members of the profession to attach a less overwhelming importance to the administration of medicinal agents, and to have recourse to the employment of them instead of what may be called physiologic

remedies for the treatment of the morbid conditions of the mind and brain. Light, air, nutriment, environment, the warding off of hurtful, the presentation of soothing impressions, these are more frequently and more successfully employed than the large class of nervines, of the remedial actions of which we are not so certain as we could wish. And when we add to these the so-called moral treatment, comprising amusement, occupation, and the like, we have enumerated most of the agents on which we most confidently rely.

The numerous and potent additions that have been made of late to our stock of nervine remedies should not be underrated. They are to be considered as constituting a great arsenal of warlike weapons of the newest construction and the most perfect adaptation to their purpose, kept always ready for use and in a thoroughly efficient state of order and readiness. But as it is the highest and most successful statesmanship not to be obliged to employ these powerful weapons in actual warfare, so we best vindicate the efficiency of our art by having recourse to our armaments only as sparingly as may be; confident, however, that at critical moments and in periods of active disturbance they can be employed with great and admirable effect.

It will always also be of great aid to the physician to be able in dealing with those committed to his care to recognize the influence on them of ideas of hope, of confidence, of endurance; to be able to deduct from their complaints what is the result of an impressionable nervous system and what of pure imagination; to solve, as nearly as may be, the personal equation. These capabilities will supplement beneficially the most refined and accurate physical diagnosis. We need not doubt that the multiform aspects of disease, following, as they do, closely on the track of all the numerous and diversified forms of human energies and activities, will afford ample scope for the freest exercise of the highest scientific faculty, as well as for the employment of the most minute and patient observation. The tendency of the medicine of the future will no doubt be in the direction of greater specialization. Physicians and surgeons will devote themselves, more and more, to the cultivation of a limited portion of the vast and always widening field of knowledge. Medicine must adapt itself to the varying necessities and requirements of the world. It must prove itself capable of supplying the wants of civilization, rapidly becoming more complex in its development, and therefore more varied as well as more exacting in its demands. It must press into its service all knowledge, physical and mental, likely to aid in the furtherance of its mission; accepting the help of its sister sciences, but allowing itself to be dominated by none of them. It must be alike flexible in its methods and steady in its aim; and it must be at once cautious and inspiring, always sane in practice, while bold in speculation. But at the same time it behooves all those concerned in its guidance, or responsible for the instruction of those who are to become its members, to bear in mind its position as one of the main supports of the tripod of learning, as one of the great factors in the intellectual progress of humanity; being well assured that it cannot sacrifice any portion of its intellectual elevation and dignity without a corresponding sacrifice of its truest and most practical usefulness.

Third Day—July 28th.

Address in Surgery.

Dr. Wm. H. Hingston, of Montreal, delivered the Address in Surgery. He stated that the average surgeon of to-day is less a man of thought than a man of action. He is constantly liable to disturbance, either from the particular character of his calling, or from the agitation of all around him, of which he soon partakes. He is made to eschew the more meditative habits that would the better fit him to weigh well and to adopt or reject what should be adopted or rejected, without reference to authority or without being swayed by the influence, not always safe and reliable, of superiority of position or of condition.

Perhaps, at no time in the history of the medical art have the facilities been greater everywhere than they are at present of arriving at conclusions that may not be intelligent, and of being misled by representations that may not be strictly true. With steam and electricity, and the wondrous and unceasing development therefrom of vast physical agencies, men are brought nearer to each other. Truth travels with the speed of lightning, but error also, and with like rapidity. Opinion, formed in a large center, acts especially on the imagination of those around, and more powerfully still, perhaps, of those at a distance. It does not always convince, but it impresses, and it has the force of authority rather than of reason; and concurrence in it is not always an intelligent decision, but a submission or belief.

English surgeons were little disposed to believe that a sponge probang, charged with solution of nitrate of silver, could be got beyond that watchful sentinel, the epiglottis, and be applied to the larynx. Who doubts it now? The same may be said of Sayre's assertion, discredited at the time, that after excision of the bones of the hip-joint the joint could be so arranged that the little patient could be borne from one place to another and without injury.

The American surgeon arrives, in his own way, and with marvellous celerity, at the chief points in a case—at its gist, its essence, so to speak—by a process which may not be strictly called logical, but which partakes rather of an intuitive intellectual judgment or perception. He seems to recognize truth, or something he takes to be truth, without any elaborate process of ratiocination. This marked quality in the American mind renders him prone to eclecticism, not alone in medicine and surgery, but in philosophy, and even in matters of theology sometimes.

The relatively greater freedom from death in Canada after surgical operations is to be ascribed to climatic influences. The inflammations which sometimes follow surgical procedures are accentuated, and are marked by much elevation of temperature; but the character of those inflammatory processes is of a simpler, plainer, more sthenic type, and not of that irritable form which so often perplexes hospital surgeons in the larger centers of Europe.

Canadians are subject to few ailments, and these are of asthenic inflammatory type. Thorough acclimatization is found to confer additional immunities. Those who can count the greater number of generations born in Canada are the healthier, while those undergoing the process of acclimatization do not suffer in the processive

state. These remarks do not apply to the descendants of the aborigines who have been allied to the whites.

There are no surgical diseases in Canada which have not their counterpart in every portion of Europe, except frostbites and the *mal de raquette*. Aneurisms are not common in Canada; chronic rheumatic arthritis is seldom met with; rickets is scarce; strumous ophthalmias are not frequent; and in carcinoma, especially of the breast, the glandular system is not generally primarily affected, affording thereby a fairer chance of freedom from early recurrence of this disease.

On the eastern coast of New Brunswick, in Canada, a few lepers are met with in the lazaretto there; but the disease is not indigenous to the soil.

As acclimatization effects certain changes, it affords also certain immunities from which those not similarly circumstanced cannot expect to benefit. The acclimatized bear injuries well. Living in a simple primitive state, they require occasional aid from the surgeon, and less from the physician. Colonists in thinly settled districts sometimes send long distances for surgical aid in cases of hernia or dislocations.

Domestic surgery in civilized countries might in some things learn a little from the primitive methods of the aborigines. For instance, the treatment of the newborn by the latter is judicious. The yielding abdominal walls are never compressed by an unyielding bandage, and the young bird in its nest is not more comfortable. As the varied movements of respiration are not impeded, the infant cries but seldom. It never suffers from the local troubles that the children of the whites often do. The urine is carried beyond the infant's person, if a male, by an ingenious mechanical support which directs the stream. Feculent matter is received into dry moss, which is to be found in large quantities in every wigwam where there is an infant.

If in the depths of the forest an Indian breaks his leg or arm, splints of softest material are at once improvised. Straight branches are cut, of uniform length and thickness. These are lined with down-like moss, or scrapings or shavings of wood, or with fine twigs interlarded with leaves, if in summer; or with the curled-up leaves of the evergreen cedar or hemlock, if in winter; and the whole is surrounded with withes of willow or osier, or young birch. Sometimes it is the soft but sufficiently unyielding bark of the poplar or the bass-wood. Sometimes, when near the marshy margin of our lakes or rivers, the wounded limb is afforded support with wild hay or reeds of uniform length and thickness.

To carry a patient to his wigwam or to an encampment, a stretcher is quickly made of four young saplings, interwoven at their upper ends, and on this elastic, springy couch the injured man is borne away by his companions. When there are but two persons, and an accident of this nature happens to one of them, two young trees of birch or beech, or hickory, are used. Their tops are allowed to remain, to aid in diminishing the jolting caused by the inequalities of the ground. No London carriagemaker ever constructed a spring which could better accomplish the purpose. A couple of cross-bars preserve the saplings in position, and the bark of the elm or birch, cut into broad bands, and joined to either side, forms an even bed. In this way an injured man is brought by his companion to a settlement, and often it has been found, on arrival, that the fractured bones are firmly united, and the limb is whole again. This is effected in less time than with the whites, for the reparative powers of these children of the forest are remarkable. In their plenitude of health, osseous matter is poured out in large quantity, and firm union is soon effected.

The healing powers of the aborigines, when injured, are equalled by the wonderful stoicism with which they bear injuries and afflict upon themselves severest torture. They are accustomed to cut into abscesses with pointed flint; they light up a fire at a distance from the affected part (counter-irritation); they amputate limbs, and sometimes they amputate their own limbs with their hunting knives, checking the hemorrhage with heating stones, as surgeons were accustomed to do in Europe in the time of Ambrose Paré, with more *sang froid* than many young surgeons will display when operating on others. The stumps of limbs amputated in this primitive manner are well formed, for neatness is the characteristic of all the Indians' handiwork.

The aborigines are familiar with, and practise extensively, the use of warm fomentations. In every tribe their old women are credited with the possession of a knowledge of local bathing with hot water, and of medicated decoctions. The herbs used are known to a privileged few, and enhance the consideration in which their possessors are held.

The Turkish bath, though in a simpler but not less effective form, is well known to them. If one of their tribe suffers from fever, or from the effects of long exposure to cold, a steam bath is readily improvised. The tent of deer skin is tightly closed, the patient is placed in one corner, heated stones are put near him, and on these water is poured till the confined air is saturated with vapor. Any degree of heat and any degree of moisture can be obtained in this way. Europeans often avail themselves of this powerful sudatory when suffering from rheumatism.

The aborigines have their herbs—a few, not many. They have their emetics and laxatives, and astringents and emollients, all of which are proffered to the suffering without fee or reward.

The "Indian teas," "Indian balsams," and other Indian "cure-alls"—the virtues of which it sometimes takes columns of the daily journals to chronicle—are not theirs. To the white man is left this species of deception. The necromancing *medicine man* doubtless practises deception, but he is, in turn, impressed by the energy of his own incantations; and failure on his part to cure exposes him to personal danger.

In the larger Canadian cities surgery in every department is pretty much what it is in the more favored centers of Europe. There is as much refinement in diagnosis, as much dexterity and courage in performing surgical operations, and as much nicety in the technique. All the cavites of the body, brain, chest, and abdomen have been explored and the diseased organs operated upon. Canada follows Europe closely, very closely, in all her work. She has had the boldness—may she be pardoned—to precede Europe in some departments of surgery. The tongue and lower jaw were together first removed in Canada; the innominate and the gluteal arteries were first ligated in Canada; and the credit of

the first nephrectomy, which writers give so generally to Germany, belongs to Canada and to Montreal. But why should Canada be in any way behind? The better classes of her students, not content with receiving instruction in their own medical schools, pass one, two, sometimes many years in Europe before commencing the practice of their profession in Canada. London, Dublin, Edinburgh, Paris, Vienna, Berlin are never without a contingent of young Canadian graduates, and many Canadian medical practitioners periodically visit Europe to add to their stock of acquirements and to renew the zest and relish to professional labor.

Whether a mixed or an unmixed good—the art of surgery is becoming more and still more divided into an ever-increasing number of special or particular branches of study or pursuit, each branch having its respective province or domain, which, it cannot be denied, is sometimes kept more distinctly by an exaggerated interpretatation of its importance. Yet each must ever remain cognate to and in close relationship with every other department of the art, for there are no limits or boundaries to their various departments, and a seemingly intimate acquaintance with one and a total nescience of others are crass ignorance of all, for "all are but parts of one stupendous whole."

Fourth Day—July 29th.

Address in Bacteriology.

Dr. G. Sims Woodhead, of London, delivered the Address in Bacteriology.

Had it been stated twenty years ago that one of the annual addresses delivered before this Association would be devoted entirely to a review of the subject, or part of the subject, of bacteriology, such statement would have been received as coming under the category of prophecies not likely to be fulfilled.

Bacteriology, though a comparatively new science, has already made so deep an imprint on the science and practice of medicine that the enumeration in catalogue form of the various facts upon which, according to our present knowledge, the solution of important medical and surgical questions depends, would occupy too much time. This address will indicate briefly the extension and limitation of the bacteriology of medicine. Extremists have little claim to be considered in the matter, and although most thoughtful men maintain that bacteria play a most important *rôle* in the production of disease, it is equally certain that no claim for anything beyond such important share can be claimed for the most virulent of pathogenic microbes.

A knowledge of the life-history of bacteria and the relation of these organisms to specific infective disease is essential to every scientific student of medicine.

It has been too much the fashion to look upon bacteriology as an art rather than as a science. It was supposed that when evidence had been obtained that a definite microörganism was associated with a specific disease, and that when a means had been found of preventing its access to the tissues or of destroying this organism, the limits of what bacteriology could teach would be reached. Thanks to the genius of a Pasteur, however, bacteriology is now looked upon as a branch of science the study of which may afford help in the solution of even fundamental problems in biology; it has assumed such importance, indeed, that into its service have been pressed the general biologist, the botanist, and the pure physiologist; whilst all who practise medicine and surgery feel that they must, at least, be conversant with the principles that underlie its study.

It would be a waste of time to attempt to trace the history of fermentation, of putrefaction, of septic conditions, and of the relation of bacteria to certain diseases, but it may perhaps be of advantage to insist that there has been a continuous evolution and extension of theories in regard to the nature of the action and inter-action of bacteria on the tissues and organs of the human body. First, there was the mechanical theory, in which it was maintained that death was due to the impaction of groups of microörganisms in the capillary vessels; then came the theory that these organisms used up the oxygen so rapidly that the tissues received an imperfect supply, and somatic death ensued. Both of these may be partial explanations, but unless it is known how the oxygen is cut off (even accepting this explanation as partially correct), a satisfactory solution of the difficulty is yet wanting. The administration of phosphorus is followed by imperfect oxygenation of the tissues, and fatty degeneration occurs. How this is brought about it is difficult to say; similar degenerations are found in certain diseases set up by microörganisms. Do such organisms, then, when introduced into the body, act directly by taking up and using for their own purposes the oxygen which would otherwise be applied to the nutrition of the tissues? Do they attack the tissues directly, making their way into their substance, and so devitalizing them that they are unable to perform their functions properly? Do the products formed by these organisms, being thrown out, as it were, in a nascent condition, immediately lay hold of the weakly combined oxygen in the blood, and remove it so that new compounds may be formed? Do these products act directly on the cells, and interfere with their functional activity? Or, lastly, do the cells when called upon to perform extra work in getting rid of these organisms or of their products—which in either case must be looked upon as foreign bodies—undergo such excessive stimulation that the supply of oxygen is not equal to the demand, so that the functional activity of the cells is in excess of their facilities for nutrition, and their protoplasm undergoes changes described as cloudy swelling, followed by fatty degeneration exactly like those met with in phosphorus-poisoning?

At one time it would have been deemed impossible to answer these questions; but as the study of the chemistry of bacteria has been utilized, information on these points has become more and more definite, and as such definite information has been obtained, it has become possible to indicate at least some of the processes that are going on in certain of the specific infective diseases, and to draw inferences, some of which, however, have still to be put to the proof, as to the methods to be adopted in waging war against bacteria.

One of the most important outcomes of the study of the relations of bacteria to disease is the development of a pathologic chemistry; hitherto pathologic chemistry has been elaborated and extended in order that it might be applied to the examination of certain products and ex-

cretions met with as the result of diseased conditions of various organisms; but beyond facilitating search for slightly modified physiologic products, this physiologic chemistry has rendered but little service. This pathologic chemistry has a great future.

There is not a sufficiently marked line of demarcation drawn between the curative effect of the antitoxic action and the production of immunity; the two are perfectly distinct, though they are too frequently inextricably confounded in respect to the interpretation of experiments.

It is to an ultimate modification of the protoplasm of the cells of the body under the influence of organic or inorganic therapeutic agents that future triumphs must be looked for in the treatment of specific disease where vaccination has not been resorted to or has failed. Of this direct action on protoplasm there are only two or three examples, but there can be little doubt that quinine and arsenic in malaria, and mercury and perhaps potassium iodide in syphilis, act somewhat in this manner. In the case of mercury, even the untoward results sometimes attending its exhibition afford evidence of the direct action of the mercury on the protoplasm of the cells, the cells, as it were, becoming exhausted under the influence of the mercury, and so becoming an easier prey to the specific virus.

Should it be definitely proved that antitoxins are formed as the result of the action of certain bacteria on the tissues and fluids of the body, such a method—as at present within reach—could prove of little practical value in the treatment of disease, for in the cases mentioned, in which any definite results have been obtained, very large quantities of the blood or serum from immunified animals have been used in order to obtain the results described, and it is difficult to imagine how it would be possible to obtain sufficient of the antitoxin from living animals, however vaccinated; whilst the risks to patients would be so great that such treatment would be unjustifiable.

The influence that bacteriology has had on medicine and surgery is best appreciated when some special process or condition is followed in its etiology, progress, and termination; in inflammation, for example, the study of bacteriology has revolutionized our conception of the whole subject, and, moreover, has enabled us to bring into harmony theories and interpretations of facts which hitherto have appeared to be diametrically opposed to one another. The various observations as to the changes in the fixed and parenchymatous cells were supposed to put out of court the processes of emigration of leukocytes and changes in the walls of the vessels. A battle royal waged between those who held that there could be no inflammation without vascular phenomena, and those who maintained that these vascular phenomena were merely secondary events, and the difficulty of deciding on this question may be readily imagined when it is borne in mind that in the human subject and the higher animals on which experiments were at first exclusively made it is impossible to set up any definite irritative changes without calling to our aid traumatism or some form of chemical irritation; and also that in such experimental subjects even the tissues which in a normal condition are extra-vascular have, under the slightest irritation, a tendency to return to their embryonic vascularized condition. It was then found that certain bacteria when introduced into the tissue had the power of setting up rapid inflammatory changes; then the pathologist and the zoölogist agreed to ascertain whether changes comparable to those set up in inflammation would be set up either by bacteria or through the irritant products when brought in contact with lower unicellular organisms or with simple organisms in which no bloodvessels are ever developed.

As a result of the various observations made, inflammation is looked upon as only part of a series of changes, all of which work toward a definite end, namely: first, the getting rid of foreign bodies, whether organic or inorganic, whose presence might exert a deleterious influence on the issues in which they are lodged; and secondly, to repairing the breach that has been left at the point at which these foreign bodies have been injected.

The soluble products derived from pure cultures of microörganisms are now known to be composed of a large number of different substances, to isolate which various attempts—many of them unsuccessful—have from time to time been made.

The methods of chemical bacteriology, corroborated by chemical observation, have determined that diphtheria is dependent for its specific symptoms on the diphtheria-bacillus. This bacillus does not attack healthy individuals, but if there is slight ulceration of the throat, or slight fibrinous exudation on the surface of the tonsils, or the posterior surface of the velum palati, diphtheria suddenly makes its appearance. Sometimes the exudation appears to be associated with the local action of the diphtheria-bacillus itself, but usually the diphtheritic process appears to be secondary to small patches of ulceration and exudation. Experiment offers the explanation of this fact. The diphtheria-bacillus does not appear to have the power of attacking healthy mucous membrane; but when it finds a nidus in coagulated fibrin it is able to produce its special secretion or enzyme, part of which acting on the fibrin, just as the enzyme met with in the stomach acts on food, rapidly transforms the insoluble and undialyzable fibrin into soluble albumoses, some of which in turn are utilized for the nutrition of the microörganism, whilst the remainder of the enzyme and the products of its action on the fibrin, absorbed by the lymphatics and bloodvessels, are carried into the system, where they act on the tissues and organs, and, after being broken down into lower molecular combinations in certain organs, are excreted.

Books and Pamphlets Received.

Conjunctivitis as a Cause of Poor Vision. By W. H. Bates, M.D. Reprint, 1892.

Treatment of Chronic Inflammation of the Mucous Membrane of the Eye, Ear, and Throat. By W. H. Bates, M.D. Reprint, 1892.

Glaucoma: Its Nature and Treatment. By J. H. Woodward, M.D. Reprint, 1892.

Post-febrile Insanity. By Henry M. Hurd, M.D. Reprint, 1892.

The Bacteria in Wounds and Skin-stitches. By Hunter Robb, M.D. Reprint, 1892.

The Use of Morphine and Other Strong Sedatives in Gynecological Practice. By Hunter Robb, M.D. Reprint, 1892.

Some Remarks on Pulmonary Tuberculosis, etc. By Louis F. Criado, M.D. Reprint, 1892.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXI. SATURDAY, AUGUST 13, 1892. No. 7.

ACUTE INFECTIOUS EPIPHYSITIS.

BY W. M. L. COPLIN, M.D.,
ADJUNCT PROFESSOR OF HYGIENE AND DEMONSTRATOR OF PATHOLOGY IN JEFFERSON MEDICAL COLLEGE.

AND

D. BEVAN, M.D.,
ASSISTANT IN DEPARTMENT OF HYGIENE, JEFFERSON MEDICAL COLLEGE, OF PHILADELPHIA.

DEFINITION.—Acute infectious epiphysitis is a disease peculiar to infancy and adolescence, and is due to the specific pathogenic action of one or more of the microbes of suppuration. It is a disease the etiology of which modern bacteriologic research has revealed, and which for more than a century and a half had baffled the most diligent inquiry of able scientific observers.

SYNONYMS.[1]—The disease is best known in the United States by the names of acute infectious osteomyelitis and acute infectious periostitis. Acute infectious arthritis is also applied to a special form of epiphysitis.

HISTORY.—In 1805 J. L. Petit described an acute affection of bone, which we now recognize as acute osteomyelitis. This is the first distinct mention that we have of this disease. Allusions were made to it also by Gooch, Pott, Cheselden, Hay, and Abernethy.

Bearing on this subject, M. Renaud, in 1831, published a paper "On Inflammation of the Medullary Tissue of Long Bones," and reported five cases occurring after amputation, all of which terminated fatally.

Cruveilhier refers to it as "phlebitis of bones," when suppuration supervened on amputation, and attributes to it the formation of visceral abscesses.

Jules Teilhard La Terrisse first employed the designation acute arthritis of infants in 1831, in his thesis submitted for the degree of Doctor of Medicine, to the Faculty of Medicine in Paris, in which he reported three cases in children, aged respectively three, six, and nine days. At the necropsy pus was found in each case in several of the joints, and in one case a number of abscesses were found in the lung.

Nélaton is credited by Roux as having devised the term osteomyelitis in 1834; in 1844 he published a brief account of it under the title of "Suppuration of Bone."

Mr. Stanley, in 1849, in his monograph on "Diseases of Bone," gives an accurate description of the kryptogenetic, or the then so-called spontaneous variety. Schültzenberger directed attention, in 1853, to this disease as "Rheumatoid Periostitis."

Chassaignac, having studied it in the same year, and recognizing its infectious character, gave to it the name of "Acute Infectious Osteomyelitis," and, for the first time, applied to the spontaneous variety, in 1855, the name "Osteomyelitis," and detailed four cases that came under his own observation.

In 1855 the affection was described by Becker as "Phlegmonous Periostitis." Almost at the same time Klose published an account of thirteen cases under the term "Meningo-osteo-Phlebitis." In each case there was epiphyseal separation. "Epiphyseal Ostitis of Adolescence" was the term applied to it by Gosselin, at about this time.

Gamet's thesis on this affection appeared in 1862. He entitled it "Juxta-epiphyseal Osteo-periostitis." Geraldès designated it "Phlegmonous Periostitis." V. Roser bestowed upon it the name of "Pseudo-rheumatism," on account of the number of bones involved and the frequency with which the joints were implicated. Luecke is given credit with having first called attention to its infectious character. Lannelongue gave a description of it in 1878, under the heading of "Acute Osteomyelitis of Adolescence."

Mr. T. Smith, a surgeon in St. Bartholomew's Hospital, has reported two cases of "Acute Arthritis of Infants." In his treatise on the *Disease of Joints*, Barwell describes the affection as "Peracute Articular Ostitis;" he also uses the term epiphysitis, taking his definition from Stromeyer's memoirs on *Ostitis Articular Peracute.*

From the frequent occurrence of the separation of the epiphysis from the diaphysis, Klose describes it as "Epiphysentrennung," also as "Meningo-osteo-Phlebitis." Krause called it "Acute Purulent Synovitis in Infants."

MacNamara, in the first edition of his work, speaks of "Acute Epiphysitis"; but, exception being taken to this term as applied to this disease, in the third edition he refers to it as "Suppurative Ostitis." In the work of Thomas Jones on *Diseases of Bone*, he discusses it under the subject of "Acute Osteo-myelitis and Necrosis of the Epiphyses and Articular Extremities of Bone."

[1] The various synonyms used will be fully discussed in considering the history.

NORMAL HISTOLOGY OF BONE.—Before considering the etiology or the pathology of acute infectious epiphysitis it is necessary to form a clear and comprehensive idea of this subject, that we should recognize and differentiate between the conditions existing at, and previous to, the completion of ossification, the arrangement of the vascular system, and other special anatomic and histologic peculiarities of the bones, all of which exercise a potent influence in determining pathologic conditions in these structures.

Bone is produced by a temporary cartilaginous substance being converted into medulla. This change is induced by the cartilage becoming pierced by channels or bloodvessels with but an imperfectly developed coat of soft connective tissue, as it is necessary that actual contact should take place between the blood and the cartilage-cells before further development can occur. The cartilage-cells, thus receiving an additional amount of nutriment, are stimulated to increased activity. With the further development of the bone, the periosteum and endosteum are produced, and then we have the bone growing from the cells contained in the medulla, the endosteum, and the periosteum.

The periosteum is developed by the outer layer of cartilage assuming a reticulated fibroid character, in the meshes of which are contained osteo-genetic cells, and it is by their further and continued development that the bone is increased in thickness.

The bone receives its nourishment not only from the nutrient artery, but also from innumerable small arteries that penetrate into the bone from the periosteum, being derived from arteries of adjacent structures. The arteries are distributed throughout the compact portion of the bone by the system of Haversian canals. In the cancellated structures some vessels follow along the trabeculæ, while others span across the space occupied by the soft marrow. In this situation they bear a strong resemblance to the blood-sinuses in the spleen. The sinuses are larger than the arteries that empty into them. In addition to the veins accompanying the nutrient artery, those arising in the compact tissue and those making their exit through the articular cartilage, there is a venous plexus surrounding the bone at the junction of the epiphyseal cartilage with the diaphysis, greatly facilitating the flow of the blood from this situation. The epiphyseal cartilages receive their blood-supply from the arteries of the medulla.

Continuous with the endosteum in the medullary cavity is a network of adenoid tissue, which is also found accompanying the bloodvessels in the Haversian canals. This is regarded by many authorities as the commencement of the lymphatic system in the bone. In the meshes of this structure are numerous cells both morphologically and functionally resembling the corpuscles in the spleen. The subcartilaginous layer of bone is a dense plate of compact osseous tissue, situated between the epiphysis and diaphysis. It is pierced by numerous vessels entering the epiphyseal cartilage from the shaft. From its peculiar structure it possesses great resistance to all inflammatory processes. In it there is no definite Haversian system.

The medullary substance occupies the central cavity of tubular bones, and is also continuous with the soft tissues contained between the trabeculæ in the cancellated portion of the bone. At the extremity of the diaphysis it terminates in bulbous processes, and from these numerous other processes are given off, which penetrate the subcartilaginous disc, and, uniting with one another, form arches.

ETIOLOGY.—The specific cause of acute infectious epiphysitis is not a special organism, as Becker at one time supposed, but—as determined by Krause, Garré, and Rosenbach, whose researches and observations have been substantiated by many of the more able bacteriologists of the day—this disease is produced by one or more of the varieties of pyogenic microbes the entrance of which into the circulation is usually effected through some abrasion of the skin, or, less frequently, through the mucous membrane of the respiratory or alimentary tracts; a decayed tooth, or any suppurating inflammatory focus, however small, may be a *portio invasionis*. The organisms have, apparently, a predilection for the long bones, and more frequently attack the one extremity, that from which the development of the bone is principally accomplished, *e. g.* the lower epiphysis of the femur and the upper epiphysis of the tibia.

The short and flat bones are not exempt from the process, and that they are not frequently involved may be ascribed to the fact that their position and function render them less liable to injury, and that the evolving changes in their development are not of such an active character as we have observed in the long bones.

The selective affinity of the microbes for one or the other extremity of a bone, or for any particular class of bones, is not incomprehensible when we study the anatomic structures. We discover that in the medullary tissue, in proximity to the epiphyseal cartilage, where the transitional changes and the vascular supply attain their maximum, and where the blood-pressure and velocity are at a minimum, where the capillaries are mere excavations, sinuses, or have but an imperfectly developed wall, we have all the conditions most favorable for the localization and multiplication of microorganisms, the pathogenic action of which is in health counteracted by the inherent vital resistance of the cells.

Roswell Park asserts that the marrow is "predisposed to collect and retain germs, and that it is most sensitive in its reaction"; from its constitution it also affords a soil that is particularly adapted for their nourishment and proliferation.

As early as 1874, Klebs, Recklinghausen, and others, discovered the presence of cocci in the bodies of patients dying of acute infectious epiphysitis, Pasteur found micrococci, and in 1881 Schüller amputated a limb, and found the same organisms in the bone, periosteum, and articular cartilages. In the same year Rosenbach cultivated from one case the staphylococcus aureus and albus, from another the staphylococcus albus alone, and from a third the staphylococcus aureus and the streptococcus pyogenes. He also produced the disease in animals by injecting the pus from a furuncle, after subcutaneously fracturing the bone, and with the pus from osteomyelitis produced in the subcutaneous tissues a furuncle.

Becker, in 1883, made most careful and extended observations, and thought that he had discovered the specific microbe of osteomyelitis. Rodet has produced osteo-myelitis by the intravenous injection of cultures of the staphylococci, and without fracturing or otherwise injuring the bones; this, however, was possible only by intravenous injection, never in his hands by the mere introduction into the subcutaneous connective tissues. Krause, in 1884, cultivated from the pus the staphylococcus aureus and albus, and found the same organisms in effusions about the joints.

Subsequently, he produced the disease in animals by injecting pure cultures of these cocci, and making subcutaneous fractures. Garré corroborated the experiments of Krause, and also discovered the staphylococcus in the blood. Krause observed lesions in the muscles, kidneys, and other organs identical with those found in pyemia.

Kocher experimented by injecting foul and putrid material into animals, and was sometimes successful in producing the disease. His failure in the other cases was probably due to the fact, that the substances injected contained none of the pyogenic organisms.

In children that have inherited constitutional taints, as those of tuberculous and syphilitic parents, the resistance to the action of pyogenic organisms is much diminished, so that we find that they are predisposed to osteomyelitis, as also are those that have, or are convalescing from, any of the acute infectious or exanthematous diseases. Thus, T. Holmes, in *The Surgical Treatment of Diseases of Infancy and Childhood*, reports the case of an infant but seven months old, in which suppuration of the hip-joint succeeded an attack of chicken-pox.

Dr. K. McLeod's case of epiphysitis, reported in the *Indian Medical Gazette* for 1883, was attributed to variola. Leucke, Keen, and Renne have demonstrated, and as experience and history of the cases confirm their conclusion, it may be received as a truth, that the specific poisons of diphtheria, typhoid fever, scarlatina, measles, rubeola, and variola, prepare the medullary tissues for the reception of the pyogenic germs.

An influential rôle is assigned to exposure to cold and damp as a predisposing factor, and as the exceeding activity of the tissue-changes in growing bone involves an instability, any sudden change tending to disturb the equilibrium of the circulation will create the conditions necessary for the inception of osteomyelitis. Professor Senn avers to have repeatedly observed cases of osteomyelitis in boys, who, after active and exciting exercise, have plunged in cold water or have stretched themselves out upon the cold ground to rest.

Pathology.—There are three situations that, according to Howard Marsh, furnish a ready nidus for the localization of microbes, as follows:

"Immediately subjacent to the cartilaginous disc; in the vicinity of the ossifying center; in the line of union between the epiphysis and diaphysis."

Their localization in the diaphyseal side of the epiphyseal cartilage, as in the soft tissues, determines an inflammation in which we may observe the same tissue-changes that occur in other structures subjected to the action of these organisms.

There is at first an increased supply of nutrient, quickly followed by a rapid multiplication of the nuclei of the fixed cells.

These cells surround themselves with a layer of granular material, and the whole is encased within a shell of earthy matter, supposed to be elaborated by the nucleus. A poor and lowly organized form of bone is thus produced. This is the analogue of the granulation-tissue found in other structures of the body. The cells, as a result of their rapid proliferation and the unyielding character of the osseous tissue, are crowded together to such an extent that their development is materially interfered with; consequently they offer but feeble resistance to the action of the germs and their ptomaïnes.

When the epiphyseal cartilage is primarily affected, the nuclei of the cells undergo rapid division and subdivision, forming masses of cells, and these conglomerations, the progeny of the cartilage-cells, becoming permeated by bloodvessels, are converted into medulla, which may continue to develop until it reaches the surface of the articular cartilage, and then we have what is frequently described as an articular ulcer. The process may also extend in the other direction, and communicate with the medullary cavity. Subsequently, we shall have a

sinus formed, and an open passageway for the pus between the interior of the joint and the medullary canals.

We perceive that the tissues adjacent to the inflammatory focus are saturated with the transuded serum of the blood, and there are present numerous leukocytes that have migrated from the vessels. We discover, also, that the tissues are stained. This is attributable, not to the presence of serum and leukocytes, but to the hematin that is liberated as the result of the injury sustained by the capillaries, diapedesis supervening, and the red corpuscles having undergone disintegration.

The compact portion does not escape, for we find that the lacunar corpuscles undergo a granular degeneration, and the bone, dependent upon the corpuscles for nutrition and repair, degenerates. Several of the spaces coalescing, a cavity is formed, which ultimately opens into an adjoining medullary space. The shape of this cavity corresponds with the original growth of the lacunar system, thus assuming a more or less circular form. The canaliculi are also filled with this granular material, as are the Haversian canals. This granular substance resembles highly vascularized granulation-tissue. Absorption of the walls of the Haversian canals is the natural sequence of this process. The canals are in consequence greatly increased in diameter, and rarefaction of the bone is effected. The vessels, not being permitted to contract, remain patulous, thereby facilitating the entrance of microörganisms and their toxines into the circulation.

The veins also participate in the inflammatory process, and we have established a phlebitis, with the formation of infected thrombi. Subsequently, portions of these thrombi become detached and washed into the circulation, and are arrested in some of the viscera. At the site of these infected embolic infarcts we have founded new foci of inflammation, and metastatic abscesses are thus engendered.

One of the peculiar features of osteomyelitis is the local or pyemic condition in the bone, and this is beautifully illustrated in the case here reported (see illustration), in which there were several metastatic abscesses in the medullary substance.

Diastasis is the result of localization of the germs at the juncture of the diaphysis and the epiphysis, or when the integrity of the bone is destroyed by extension of the inflammation.

History of the Case.—In reporting the history of this case, it has not been deemed necessary to go fully into the symptoms, but only to bring out the more important features, which make it differ slightly from other cases reported in the current literature on this subject. The symptoms of this disease have been so fully gone into by the various writers who have considered it, that it is not deemed at all necessary to present an elaborate history, which would, in many points, be but a repetition of well-known and well-established facts.

In the first place, the case was rather peculiar in that the child was thirteen years of age, and that the symptoms had never been active in early life. From the time when she began to walk she had complained of pains in the tibia, occurring more frequently at night, and often preventing sleep. There had been slight swelling, at about four years of age, situated just externally to the tubercle of the tibia, but this had subsided, and had given rise to no symptoms. About one year previously to the time when first seen she had received an injury, caused by a flat-iron falling on the metatarsal bone of the great toe. This had been followed by severe inflammation and the development of a small abscess, which was opened at the time. Some small fragments of bone were removed, and the cavity was freely drained. The wound healed without any apparent difficulty. The pain in the tibia, which had annoyed her for years, became more intense; her general health failed; she lost flesh; her appetite disappeared; and, from a bright, cheerful child, she became morose, disinclined to play, and showed other well-marked symptoms of diminished physical activity. Six weeks before the time when she was first seen there developed points of intense tenderness, situated immediately above and below the knee-joint, and the family states that these points were slightly soft. This was followed in about ten days by symptoms of active inflammation in the knee-joint.

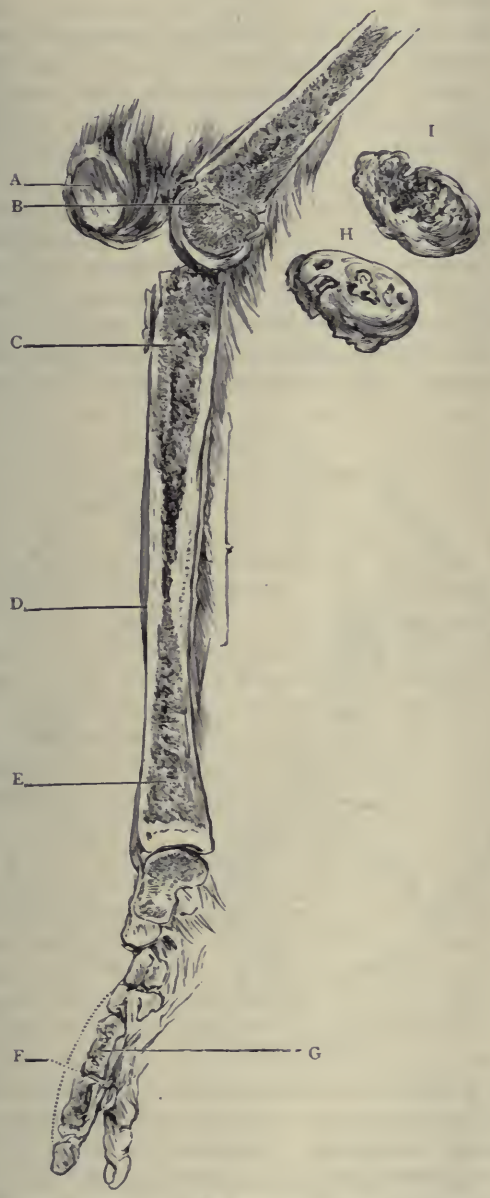
The entire crest of the tibia was painful and tender to the touch; there was some enlargement of the lower extremity of the bone; there was fever; several distinct chills occurred, followed by sweats and extreme weakness. The emaciation increased; sleep became impossible, except after the administration of opiates to lull the pain in the infected joint and quiet the nervous system. The symptoms did not seem to respond to any local or systematic treatment, and six weeks after their beginning she first came under our observation.

The physician who had attended the case diagnosticated the condition as one of white swelling, and had so treated it. She was seen by Dr. Allis, Dr. Hearn, and Dr. Coplin, and after a careful study of the case the diagnosis of infectious epiphysitis was made, and an exploratory operation was decided upon. When the knee-joint was opened, the enormous extent of the pathologic process seemed to demand the amputation of the limb, and after gaining the consent of the parents this was done. The accompanying illustration shows the extensive infiltration of the bones affected. There was the "flail joint," and the development of other well-marked

symptoms which are usually associated with the disease.

After amputation the girl rapidly recovered.

Fig. 1.



A. Patella turned backward and to one side, showing its lower surface.

B. The lower extremity of the femur, showing the line of the epiphysis and a distinct border of fatty degeneration just where the epiphysis joins the shaft. In the lower extremity of the femur are several small round or irregular dots that mark the position of metastatic abscesses in the bone. The periosteum of the femur is slightly thickened just above the epiphyseal line. The epiphysis is normal.

C, D, E. Sawn section of the tibia, showing the condition of its medullary canal; at the upper extremity of the tibia the shaft terminates in a jagged, irregular extremity that has been in apposition with the epiphysis. The epiphysis is placed over on one side at H, with a view of the upper surface, while at I the view is that of its under surface. Just above the line that leads from C are two metastatic abscesses of considerable size; below this line, and extending to the line D, is to be noted the detachment of the periosteum. The periosteum is much thickened, the thickening fading off as the line E is approached. At C the bone-marrow was intensely red and congested, and there were no less than a dozen small abscess-cavities not quite as large as split peas. The external compact portion of the bone is much thickened, and just opposite the pointer there is considerable swelling along the line of the periosteum. The lower epiphysis of the tibia does not show well; at the lower extremity of the shaft, however, can be seen several small abscess-cavities. The point G is the seat of the original injury. F marks the metatarso-phalangeal articulation, the lower extremity of which should be placed to the upper extremity, as that represents the sawn section of the bone of the great toe. The great toe is also shown.

H is a view of the superior surface of the epiphysis of the tibia, the articular surface. In it there will be observed not less than five or six small openings that communicate with the abscess below and with the joint above. In some of them small fragments of necrotic bone are to be observed. The cartilaginous structures of the joint are also entirely destroyed, and the articular margins of the epiphysis show a slight fragment of the two semi-lunar cartilages.

I is the same as H, except that it is a view of the inferior surface where it came in contact with the tibia. It will be observed that in the epiphysis there is nothing more or less than an abscess-cavity, the wall of which is formed by a hard cancellated layer of bone and by the articular disc. There was no periosteum continuous with the shaft and epiphysis, and hence the epiphysis moved freely upon the end of the shaft, thus giving the well-known "flail joint" so characteristic of epiphysitis. The interior of the knee contained a considerable quantity of pus, and the synovial structures were also disorganized.

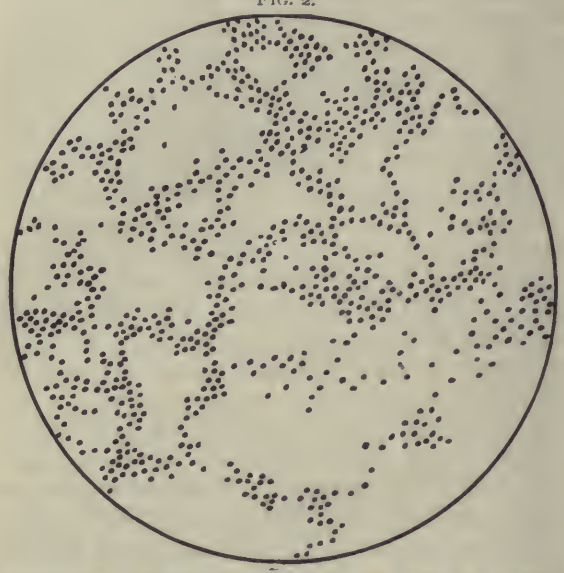
Laboratory.—The tubes inoculated from the pus immediately surrounding the joint were, by plating and carrying the cultures rapidly through several generations, proven to contain the following organisms: The staphylococcus pyogenes aureus; the staphylococcus pyogenes albus; the bacillus pyogenes fetidus; the proteus mirabilis.

Experimental Pathology.—Rabbit No. 1 was injected at 5 P.M. with a culture of the staphylococcus aureus of the first generation. It remained apparently perfectly well until the day following, when it appeared rather weaker than usual. Its eyes were dull; it ate but little food; and it seemed inclined to doze a greater portion of the time. When seen later in the day, it was extremely restless; prostration was marked; and there was an inability to coördinate muscular movements. Respiration was shallow, quickened, and irregular; the heart was quick, weak, and the rhythm altered. During the latter part of the day it had refused to eat and associate with other rabbits. It sought a corner of the cage, where it remained, and was found on the next morning, dead. On post-mortem examination, no microscopic lesions were observed. Death had resulted from septicemia; tubes cultivated from the blood showed growths of the staphylococcus aureus. This was confirmed by microscopic examination.

Rabbit No. 2 was injected at 8 A.M., June 17th, with the staphylococcus albus of the first generation.

The first symptoms noted manifested themselves on the following day, at 2 o'clock. When offered food, the animal refused to eat, and the same symptoms succeeded that were observed in the preceding case,

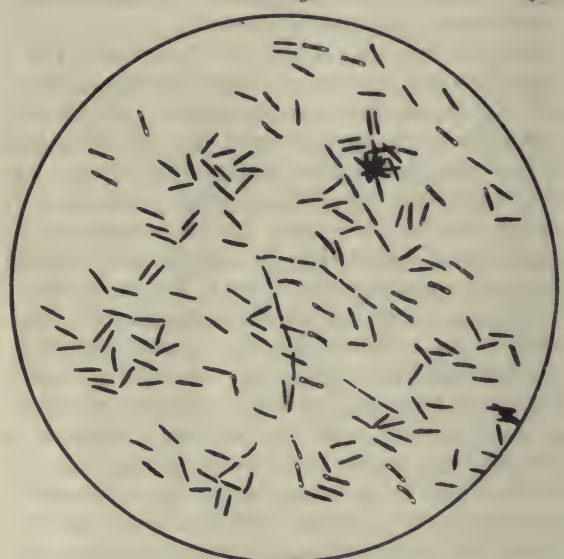
FIG. 2.



Micrococcus (staphylococcus) aureus—from agar-agar culture; Beck's $\frac{1}{12}$ homogeneous immersion; Oc. 2.

although the animal did not so readily yield to the influence of the microbes, not dying until the evening of the 20th. Cultures of the blood and urine showed growths of staphylococcus albus.

FIG. 3.



Bacillus pyogenes fetidus—from agar-agar culture; Beck's $\frac{1}{12}$ homogeneous immersion; Oc. 2.

Rabbit No. 3 was inoculated on the evening of June 24th with a mixture of the aureus and albus. It died on June 26th, at 3 o'clock, with the symptoms of an intense septic infection. In tubes inoculated a growth of the two cocci developed, as was proven by plating, staining, and microscopic examination.

On June 26th, two rabbits were inoculuted, small quantities of the organisms being employed; one, No. 4, with proteus, and the other, No. 5, with the bacillus pyogenes fetidus. No lesions were observed at the seat of inoculation. The animals were killed ten days later. There were no internal lesions. The organisms had probably been destroyed by the phagocytes and eliminated by the emunctories; their absence from the blood being proved by culture-experiments with the intra-cardiac blood and with blood from the kidneys, liver, and spleen.

On Monday, January 12th, rabbit No. 6 was inoculated with staphylococcus aureus, just above

FIG. 4.

Proteus mirabilis—from agar-agar culture; Beck's $\frac{1}{12}$ homogeneous immersion; Oc. 2.

the ankle-joint, on the right side. The injury was inflicted by means of a small sterilized gimlet, an attempt being made to puncture the bone, but on account of the dulness of the instrument, and the extreme hardness of the bone, the periosteum alone was injured, the seat of the injury being as near to the epiphyseal line as could be made, without having previously ascertained its location. The injury to the bone, as well as the injection of the microörganisms, was effected with the strictest antiseptic precautions, care being taken that the point of the puncture through the skin should not be located immediately above the point of injury of the bone, the point of inoculation being fully one inch below the point of injury.

On the day following the treatment, the rabbit

was dull; it did not eat. At the seat of inoculation was a small point of tenderness, with a distinct area of inflammatory redness. This small point of redness developed slowly into an abscess, requiring nearly a whole week to attain sufficient size to render the diagnosis positive. At this time there were well-marked constitutional symptoms, such as severe rigors, emaciation, weakness, staggering gait, and inability to stand. This condition continued for about five days, when it was noted that the injured limb had rotated directly backward, the plantar surface of the foot being upward; there was well-developed "flail joint"; the limb was considerably swollen, the abscess having evidently extended up the middle third of the femur. The rabbit at this time seemed to have improved in its physical condition; it evinced a desire to eat, and would also run around the cage in which it was confined. The emaciation did not seem to lessen; neither did the rigors entirely cease. The abscess seemed to have diminished in size, but the general usefulness of the limb did not seem to improve in the least; it was limp and useless to the animal.

The animal died on February 12th, and the following post-mortem notes were made: It was evidently emaciated to the last degree. Before any incisions were made in the skin, the condition of the limb was noted as follows: Instead of any well-marked articulation at the knee-joint, the limb was found to move in all possible directions, and crepitus could readily be obtained. What had been the abscess now seemed doughy and firm, and pitted on pressure. The skin was very carefully dissected from over the seat of the abscess, after which this was opened. The cavity was filled with a cheesy material, which emitted a sweetish odor. It was too thick to flow, and contained large flocculi, evidently necrotic tissue. The knee-joint was entirely disorganized; its capsule was destroyed; the articular cartilages were necrotic; the epiphysis of the femur was separated, and divided into minute fragments, the extremity of the bone being eroded, irregular, and the periosteum removed from its surface as far as the middle third. The abscess had infiltrated the muscle to a slight extent, and in the inguinal region there was an enlarged lymphatic gland, about the size of a shell-bark. The other joints were found perfectly healthy.

The heart was the seat of a slight pericarditis, as shown by the small quantity of flocculent lymph found in the pericardium, also attached to the visceral and parietal layers. This all washed off, and did not seem adherent. The pleura was normal, the lungs thoroughly collapsed, and the seat of several spots of petechial redness; they did not seem to be the seat of any abscesses, and crepitated at all points.

The liver showed marked swelling; its borders were not so sharp and smooth as usual; upon its surface were several distinct creamy white spots, about as large as the head of an ordinary pin; these seemed at first to be on the surface of the liver, but closer examination showed that they were beneath the capsule, and in the liver-tissue itself. The liver was very friable, and granular in appearance; it also seemed to lack the usual intensely red color found in most rabbits. On section, several spots, identical with those beneath the capsule, could be seen; some of these were removed for microscopic examination. The bile was light in color, and did not stain.

The kidneys were apparently swollen, and their capsule tense; after section, the cut surface could not be placed smoothly together. Along the cortex there were striated lines of congestion, many of them extending far down toward the pelvis of the organ. There were several distinctly white spots of extremely small size, which it was thought might be minute abscesses. To ascertain this, small pieces of the organ were removed for microscopic examination. The organ had no urinary odor, and the urine in the bladder seemed normal.

The other abdominal organs were healthy, except that the spleen was swollen and friable; the peritoneum seemed dryer than usual, and its surface did not look glistening, although no other evidence of inflammation could be detected. There was no apparent enlargement of the mesenteric glands; the retroperitoneal glands were enlarged, and a few had undergone suppuration and caseous formation in their interstices. The general muscular system and joints, other than already noted, were carefully examined, but no evidence of infection could be found.

A microscopic examination of the liver and kidney is appended.

The liver showed numerous thrombotic blood-vessels, and into the perivascular structures and the intercellular spaces rhexis had taken place; the leukocytes had emigrated, and were present in large number. The vessels radiating from the hepatic veins showed stasis, and in points the entire vascular apparatus of the lobule was plugged. The liver-cells were granular, their nuclei not staining. Many of the thrombi were the seat of beginning abscess-formation, as indicated by the young-cell exudate and mycotic invasion. The liver-cells showed the usual changes due to hyperpyrexia; they were granular, stained poorly, and in no small number neither nuclei nor nucleoli were visible; the epithelium of the bile-ducts was not altered.

After staining, so as to bring into relief the organisms, if any were present, the examination was con-

tinued with high powers: everywhere in the blood-vessels, perivascular and intercellular spaces, were hosts of microbes; and, what was peculiarly characteristic, mural implantation had occurred and colonies of organisms could be demonstrated within the walls of the hepatic vessels. There appeared to be present bacilli, for which we could not account; but Professor Longstreth expressed an opinion that they were refraction-lines. Staphylococci were present in abundance, and even a casual observer could not fail to note how thoroughly disseminated through the textures they were.

The kidneys, with low powers, showed infarcts, with areas of hemorrhagic extravasation. Small round cells were present in abundance in and about these areas, indicating inflammation and beginning abscess-formation. The epithelium of the tubes was granular, and degenerating in the highest degree. Indeed, few points were visible in which any of the histologic structures were normal. Many of these changes, like those in the liver, might be attributed to the high temperature. Many of the vasa recta were thrombotic.

With high powers, organisms were found in all portions of the kidney, and especially in and around the thrombi. Some of these microbes could be observed in the interior of the round cellular elements. There were also present rod-shaped bodies, resembling those found in the liver, for which the same explanation is offered as that already given. It is also to be remembered that cocci situated in the interstices of tissues may be stained, and look very much like rod-shaped bodies. This observation is borne out by the fact that by no amount of plating could aught but cocci be cultivated.

REMARKS. — There is no specific microbe of epiphysitis or osteomyelitis. The two are practically the same disease—that is, when the latter occurs in adolescence, due to the same organisms, and differing only in the primary site of localization of the germs.

The order of frequency with which the germs are found is as follows: Staphylococcus aureus, staphylococcus albus, staphylococcus citreus, and rarely the streptococcus pyogenes. Unless dependent upon some anomalous condition, epiphysitis never occurs after the completion of ossification, the peculiar construction of the parts and the distribution of the vessels being necessary and essential elements in its causation.

It is of interest to note, that in the effusion into the tissues, the advance-line of mycotic invasion, saprophytes were not present; neither could they be found in the metastatic abscess in the tibia, nor could any effect be observed by injecting them into healthy tissues of rabbits in quantities insufficient to produce death.

In considering the foregoing fact, it may be confidently asserted that the coëxistence of the bacillus pyogenes fetidus and proteus in the pus, was due not to primary, but to secondary infection. The staphylocci constitute the essential exciting cause of this affection, and they prepare the tissues for the reception of saprophytes. The toxines produced by the saphrophytes increase the danger of septic poisoning.

The staphylococcus aureus excites a more active inflammation than does the staphylococcus albus, and the staphylococcus albus is more active than the staphylococcus citreus, and a mixed infection, especially of the staphylococcus aureus and staphylococcus albus, is the most virulent of all. These facts may be explained by attributing to each variety of microbe the capability of engendering a ptomaïne peculiar to itself. As the result of chemical action from the presence of two such compounds in the tissue, another compound is formed, which, though not differing essentially in its action, acts upon the cell-protoplasm with greater intensity; or the hypothesis may be advanced that the amount of ptomaïnes generated by an organism is not dependent upon the number, but upon the quantity of the material supplied that it can utilize as food. Hence, it may be assumed that there are present in a part substances that are unaffected or cannot be assimilated by one organism, which to another will serve as an excellent pabulum, and from which the organism will elaborate its peculiar ptomaïne. Therefore, it is evident that if this be the case, we shall have in a given amount of material a greater production of ptomaïnes in mixed infection.

Localization of the organisms is determined by any condition that lowers the inherent vitality or physiologic resistance of the cells, or by any circumstances that disturb the equilibrium of the circulation, as pointed out in considering the etiology. In the case reported by Rosenbach, in which a child was born suffering with infectious epiphysitis, the mother showed no sign of disease; and in a similar case, personally related by Dr. Joseph Hearn, in which he operated upon a child but three weeks of age, suffering with a peri-articular abscess, the little patient, with the exception of a small sinus, which occasionally discharges a little pus, is apparently perfectly healthy.

A pyemic condition of the bone is a constant attendant upon acute infectious epiphysitis, and if the disease is allowed to progress unchecked, a general pyemia invariably ensues.

In the illustration the number of apertures communicating through the epiphyseal cartilage with the cavity of the abscess, and with that of the joint, will be noted.

MECKEL'S DIVERTICULUM AS A CAUSE OF INTESTINAL OBSTRUCTION.[1]

By DUDLEY P. ALLEN, M.D.,
VISITING SURGEON TO CHARITY AND LAKESIDE HOSPITALS, CLEVELAND, OHIO.

Some three years ago it was my good fortune to operate successfully upon a case of intestinal obstruction caused by Meckel's diverticulum. The rarity of operations of this sort, together with the favorable result, has given the case added interest to me, and has led me to give the subject some consideration. Before entering upon a general discussion of the subject a short review of the case in question may prove of interest:

The patient, A. A., was a laborer, thirty-four years of age, of excellent health, his only sickness having been an attack of typhoid fever in 1876. Since that time his bowels have been regular, and he has been well. On the night of August 22, 1889, he was seized with intense pain in the abdomen. On the following morning his wife gave him senna tea, and he had a stool on the same day, and daily from that time until the night of August 29th. During this period he was perfectly well, and performed hard labor. On the night of August 29th he was seized with severe pain and vomiting. On the following morning a physician gave him a hypodermatic injection of a quarter of a grain of morphine and an enema of three quarts of water. The latter came away without fecal substance. On August 31st I saw the patient with my friend Dr. Krause. The patient had no fever; his pulse was slow, but not strong. The abdomen was distended, especially in the epigastric region. The whole abdomen was tympanitic, except to the right side of the right mammary line. I could detect the presence of free fluid in the abdominal cavity; no induration could be felt. Twice during the day the patient received an enema of three quarts of water, which returned clear. At 4 P.M. I washed out the stomach, and obtained water discolored by food, but without odor. Immediately afterward I performed laparotomy by a median incision below the umbilicus, and found the small intestine largely distended; a considerable amount of free, amber-colored fluid escaped from the abdominal cavity. A band was found extending from the region of the cecum to a point one and a half inches to the right and below the umbilicus. A coil of small intestine was twisted about this band, and constricted. The division of the band between two ligatures relieved the constricted gut. Further examination showed the cause of constriction to be a Meckel's diverticulum, perhaps four or five inches in length, in part patent, but terminating in a fibrous band. The abdomen was washed out and closed. The patient endured the operation well. After being returned to the ward he vomited a brownish material of distinctly stercoraceous odor. At 8 P.M. his condition was good; on the same night he passed flatus. He made an uninterrupted recovery. The patient was up and about on September 24th, and is now doing hard labor, having been entirely well since the operation.

In a discussion of the subject, it may be well to say a few words concerning the origin, location, form, etc., of Meckel's diverticulum. As is well known, it is the remains of the omphalo-mesenteric or vitelline duct, extending from the lower portion of the ileum through the umbilicus to the yolk or umbilical vesicle. Usually with the development of the fetus this structure atrophies and entirely disappears. Its origin is from the lower portion of the ileum. In the cases that I have examined its location has been from fifteen inches to three feet above the ileo-cecal valve; its form is various. The diverticulum may resemble a small intestine, ending like the finger of a glove, hanging free into the abdominal cavity, and having nearly the diameter of the gut itself. The opening

[1] Read before the Cincinnati Meeting of the Ohio State Medical Society, May 5, 1892.

in the gut caused by the diverticulum may vary from nearly the diameter of the gut itself to one that is very small. The diverticulum may be patent for only a short distance, or throughout its entire length, conveying fecal material to the umbilicus, and there forming a fecal fistula, or the lumen may be wholly obliterated, and the diverticulum be reduced to a simple fibrous band. At times the diverticulum is attached directly to the umbilicus or to the anterior abdominal wall. It is supposed that it may float freely in the abdominal cavity, and by chance become adherent to any part. The most common point of adhesion, as I have observed it, has been to the mesentery, in the vicinity of the origin of the diverticulum; but there are cases recorded in which it has been adherent to the posterior part of the pelvis and to the internal inguinal ring, and to the fundus of the bladder.

As to its frequency, among 3400 recorded post-mortem examinations at St. Bartholomew's Hospital, in London, it was found to be present twenty-seven times, or once in every 126. In an interesting article by Dr. Durham, in Quain's Dictionary, it is related that among 1839 cases of intestinal obstruction, seventy-five cases were found to be due to Meckel's diverticulum, or one in every twenty-four and a half cases. My own study of pathologic specimens has awakened in my mind the question whether or not more deaths ascribed to intestinal bands are not due to Meckel's diverticulum than was formerly supposed. My reason for this is that in some pathologic collections that I have studied some of the older specimens, without complete history, have simply been recorded as "obstructions due to the presence of an intestinal band," whereas in later cataloguing the curator has viewed these as probable specimens of Meckel's diverticulum, although the location of the constriction was not originally recorded in the description of the specimen. If this is true of some museums that have been most carefully arranged I feel confident that in many cases that have simply been recorded as the result of constricting bands the origin of the band has been in the omphalo-mesenteric duct.

When last in London my attention was called to the collection of specimens of Meckel's diverticulum in the museums of St. Bartholomew's Hospital and the Royal College of Surgeons, by my friend, Mr. Frederick S. Eve, through whose kindness and that of Mr. Edgar E. Willett, Curator of St. Bartholomew's Museum, I was enabled to study these specimens. Though I have carefully recorded and tabulated my observation of the specimens, together with the history as given in the catalogues, it would be impossible to produce in this paper more than a few conclusions arrived at therefrom. In St. Bartholomew's Museum are seventeen cases of diverticula; eight are without a full history; of nine the history is complete. Of these nine all died as the result of the diverticulum. Only one of them had been operated on, and in this perforation of the gut had taken place before operation. In the Royal College of Surgeons are four specimens, all of which had caused death. One of the patients had been operated on, but the cause of the obstruction was not discovered until the post-mortem examination. In all of the cases in which the history has been recorded the part of the gut constricted was the small intestine, and in most of them it was stated that it was the lower portion of the ileum. The longest time during which a patient had lived after the appearance of the symptoms of obstruction had been nine days; the shortest was thirty-six hours; the average was from three to four days.

Deaths from Meckel's diverticulum usually occur in youth or in early adult life. The youngest case that I have found recorded was in an infant, two years of age; the oldest in an adult of sixty years. The diverticulum is said to be present four times more frequently in males than in females.

Though I have looked up a large number of cases gathered in the literature of medicine, together with their history, it seems that tabulation would give uncertain results, since all cases are not discovered and reported, and many are inaccurately observed.

The symptoms of intestinal obstruction dependent upon Meckel's diverticulum are very similar to those of volvulus occurring in the lower portion of the ileum. There is pain, the location of which is not sufficiently definite to be distinctive, together with vomiting and obstipation. Treves states that if obstruction be complete, the pain is continuous, whereas, if pain is not constant, it is an indication that the obstruction is not complete. This may be a general truth, but I have seen cases in which intestinal obstruction has been complete, which for days have been free from pain, although not under the influence of an anodyne.

The diagnosis of obstruction due to Meckel's diverticulum must of necessity be rare, but there are certain considerations that would lead the surgeon to consider it among the possible causes of such obstruction. Obstruction due to Meckel's diverticulum, as has been said, is usually confined to the lower portion of the ileum, and, as is well known, the vomiting induced does not ordinarily occur so early, or with such severity, as when the constriction is higher up in the small intestine. At the beginning of the obstruction, in a patient with moderately thin abdominal walls, there may be found a local prominence in the region of the cecum. As tympanites becomes general, the distention of the abdomen will render this prominence imperceptible, but it is an important observation, and the recorded experience

of many others, that occlusion of the bowels in the region of the cecum causes distention of the central portion of the abdomen, and in the early stage more particularly in the epigastric region. In this way occlusion of the small intestine in the well-observed cases may generally be distinguished from occlusion of the colon, as the latter produces correspondingly greater fulness of the flanks. One may further distinguish between the two by means of enemata; if enemata be given, and especially if they render the region of the ascending colon dull, one can, with fair probability, at least, exclude the presence of obstruction in the large intestine. The fact becomes more apparent when we consider that sudden stoppage of the large intestine low down is commonly due to volvulous in the region of the sigmoid flexure, so that the presence of this condition could be excluded by means of enemata.

Intussusception, appendicitis, malignant growth, and fecal obstruction can, as a rule, be distinguished from any sudden closure of the lower portion of the ileum. It is not infrequently, too, that a Meckel's diverticulum may cause repeated attacks of partial obstruction, and repetition of such attacks would suggest this as their cause.

There is one point in diagnosis that I have repeatedly observed, although I have not seen it mentioned elsewhere, and which may, I believe, be an aid both in the diagnosis and in operation upon cases of intestinal obstruction, due to whatever cause; that is, the presence of free fluid in the abdominal cavity. I have repeatedly encountered it in appendicitis, strangulated hernia, and intestinal obobstruction, particularly in the two latter conditions.

When I find symptoms of intestinal obstruction, together with the presence of free fluid in the abdominal cavity, I have come to consider it a strong argument in favor of operation as affording the only chance of relief, and this fluid seems also to me to improve the chances of the operation. I have seen cases of intestinal obstruction in which at an earlier stage I was able to diagnosticate the presence of free fluid in the abdominal cavity, and as the case progressed and grew more hopeless, either at the autopsy or at operation, I have found that this fluid had disappeared. When it is present as a result of constriction of the bowel, it increases the hope that this constriction has not yet reached a point at which so serious damage has been produced as necessarily to prove fatal. This fluid, in my observation, tends to decrease as extensive adhesions due to advancing inflammation take place. Care must be taken to distinguish between free fluid in the abdominal cavity and fluid in the intestines, which may fall from one side to the other by change of position, as I have seen it occur, and have been able to demonstrate at the post-mortem. In operating for intestinal obstruction, if my suspicion is correct that it is more frequently due to the remains of the omphalo-mesenteric duct than is commonly supposed, since the clinical evidence is that this obstruction is located near the cecum, the danger of its being overlooked as a cause of obstruction will be decreased, and the operator will perhaps find with greater rapidity the cause of the difficulty.

When obstruction of the bowels takes place, and the small intestine becomes greatly distended, it is with the greatest difficulty that the bowel can be examined, unless it be permitted to escape from the abdominal cavity. This escape always adds to the difficulty of the operation, especially when the abdomen is tense, and to the danger of the patient. The prevention of the escape of the intestine has, in a series of reported cases, resulted in the cause of the obstruction of the bowel remaining undiscovered, and the death of the patient. All who have operated repeatedly for abdominal obstruction know with what difficulty distended intestines can be returned to the abdominal cavity, unless the gas be removed, and the shock and danger to which the return of the intestine or the removal of the gas subjects the patient. If the surgeon proceeds at once to examine for the possible presence of a Meckel's diverticulum, beginning with the cecum, extending his search upward, it is a matter of but a moment to ascertain whether a Meckel's diverticulum be present or not. He thus avoids the loss of much time and the large escape of the intestines resulting from a less systematic search.

Possibly the median incision is the best. When the diverticulum is found it should be divided between two ligatures, since it must be remembered that the diverticulum is often patent, and might discharge fecal matter into the abdominal cavity. Though the intestine that is constricted may be very seriously decreased in caliber, it must be remembered that this does not necessarily prevent a subsequent return to its normal capacity, and great care must be taken to distinguish between the intestine that is temporarily reduced in caliber through constriction and one that is permanently narrowed by organic changes. On account of the serious condition of patients with intestinal obstruction when operated on, it is probably best to content oneself with a division of the constricting band, and not to attempt its resection.

Though there are many points that have received but brief mention, the time at our disposal will not admit of their further elaboration, and the object of this paper will have been secured if it directs the attention of operators more specifically to Meckel's diverticulum as a cause of intestinal obstruction,

and thus enables them more quickly and more easily to recognize and overcome the difficulty.[1]

THE MORBID PROCLIVITIES AND RETROGRESSIVE TENDENCIES IN THE OFFSPRING OF MULATTOES.[2]

BY W. A. DIXON, M.D.,
OF RIPLEY, OHIO.

OBSERVATIONS extending over a period of more than thirty years have thoroughly impressed the conviction upon my mind that the offspring of mulattoes are the subjects of constitutional diseases to a greater degree than are those of unmixed blood, and that when confined strictly to their own class they scarcely reach the fourth generation in descent, by reason of disease and sterility.

I have often wondered if others have had occasion to notice this feature in mulatto life, or whether the conclusions at which I have arrived are false and unwarranted, from being based upon observations confined to a local district, yet rich in examples that go far to establish the view propounded.

I believe that there is not much to be found in current medical writings upon the subject. Our locality is on the border between the slave and the free States of fifty years ago and more. It was then, and long before had been, the custom of many wealthy planters, as they advanced to old age, to set free that portion of their estates which bore to them a filial relationship, and establish them in homes in a section of country where they would receive fair treatment, consideration and respect as citizens and members of the community in which they should reside. Such an opportunity was offered to them in our locality, largely populated by Abolitionists and sympathizers with the slave.

Thus, a community as it were of mulattoes, whose parents on the father's side were white men, mostly of great wealth and position, socially and politically, and principally of New England stock, existed near us. The most of these people were complete types of physical perfection, tall, muscular, and perfectly developed. Many of them lived to old age—quite to one hundred years. Their wives were mulattoes. They were proud of their parentage and light color of skin. They made good citizens, and often were prosperous as farmers. Their prosperity and pride almost separated them from their less fortunate brethren of darker color, and their children intermarried, that their color and race might continue.

I can trace some of these families through three or four generations. Those of the first cross were robust; those of the second were paler, more ashlike in complexion, of slender form, plainly bearing many of the characteristics of predisposition or inevitable tendencies to special diseases of the strumous type. The third union resulted in less fertility and greater predisposition to disease.

Now, the children present the scrofulous physiognomy. The fourth union, still less fertile than the others, brings forth a progeny largely suffering from cutaneous affections, ophthalmia, rickets, dropsy of the head, white swelling of the knee-joints, morbus coxarius, diseased glands, suppurating sores, uutil the whole generation is quite extinct. I can scarcely find any of the fourth generation in good health.

These people have had all the advantages that their neighbors enjoyed. They had the best of schools, excellent religious privileges; were moral, upright, and highly respected. They were able to maintain an academy of learning, from which their sons and daughters could go forth amply equipped to struggle in the unequal contest of life. All of these institutions succumbed to the waning constitutional vigor of their offspring.

The academy is no more. The schools and churches, so ably maintained by their forefathers, are extinct. The old family name is scarcely heard, and inquiry reveals the fact that their offspring were tuberculous, and either died in youth, or, if living, were so sterile that no descendants scarcely of the old families can be found. This is true not only of one but of many groups of families.

The contrast between the histories of the mulatto and the white and the negro families residing side by side, as to health, as to power to resist disease, and as to longevity, is too great to escape notice or to be regarded as merely incidental.

It is now observable by the colored people themselves that if a mulatto marries back to the parents' stock the children to a greater degree escape scrofulous affections.

I have spoken to a number of physicians in this locality upon this subject, and they all agree with me that tuberculosis exists to an excessive degree among the mulattoes; that they are inferior in vitality, intelligence, and consequently morality; that they exhibit a mortality more considerable than that of the surrounding whites or negroes, and without reunion with the parent stock the mulattoes would soon become extinct.

In the first generation they are quite prolific among themselves, and arrive at maturity rather promisingly, but when these children intermarry they and their descendants are not prolific, a large

[1] In performing a difficult ovariotomy since the reading of the foregoing paper, I found a Meckel's diverticulum extending from the ileum and attached to the right horn of the uterus, close to the Fallopian tube.

[2] Read before the Section of Diseases of Children, American Medical Association, Detroit, Michigan, June 10, 1892.

portion being sterile at even the second and third generations. It is noticeable that the mulatto girls develop in advance of both white and negro girls, but as women they fade away much sooner. It is noticeable also that in the second and third generations of pure mulatto intermixture quite all of the children born are girls, and these are noticeably sterile.

This fact I have observed so much that I believe it to be a physiologic truth. I should be glad to learn if the observations of others who have given any attention to this subject confirm my own.

If this be true in one locality and in the mingling of the white and black races there, why not look for the same result in the cross of races elsewhere, and thus the introduction of the virus of constitutional diseases which is transmitted through the succeeding generations? I believe that ethnologists mainly agree that human hybridity cannot be maintained without reversion or fresh supply from parent blood.

Dr. Robert Knox, in his work on *The Races of Men*, says: "I do not believe that any mulatto race can be maintained beyond the third or fourth generation by mulattoes merely. They must intermarry with the pure races or perish." M. Georges Pouchet says "that such a race, such a type can only have an ephemeral existence." Dr. Paul Topinard refers to a record on this subject in North Carolina. "There the caste of free men was constituted entirely of mulattoes freed by their white fathers. The State, dismayed at the important position which they assumed, put a stop to this liberation. Left to themselves their number diminished at the rate of twenty-nine per cent. decennially."

Ethnologists have sought in vain among the nations of the earth for a race manifestly hybrid, with well-defined characters, intermediate between two known races, perpetuating itself without the concurrence of the parent races.

Dr. Pritchard, in his *Natural History of Man*, in an effort to find such subsisting by themselves, could only point out three instances, the Griquas, the Cafusos and the Papuans.

Broca and others object to the truthfulness of these examples, and assert "that by no means do they prove that a mixed race can perpetuate itself separately."

If Dr. Pritchard, in his vast researches, finds it difficult to discover three examples of hybrid races subsisting by themselves, and they so liable to objection that the other ethnologists deny the proof to be conclusive, then may we not inquire into a cause for the introduction and propagation of diseases, physical weakness, sterility and conditions unfavorable, either for moral or physical development beyond the microbe or the bacillus.

The same causes that degenerated and brought to an ignoble end some of the royal lines and the most ancient blood of Europe are at work still and in our midst also.

Look, and wherever you see the greatest intermingling of races there you see raging tuberculosis, carcinoma and struma in all their terrorizing forms; there you see an excessive mortality among the children, a disparity between the number of men and women, the women being in the majority; there you see the scientist with his microscope hunting for the enemy of life and health in the sputa, the excreta and the cell-elements; when in fact the modification of the racial type, by the influence of some media not apparent in the cell-elements themselves, altered in some way by miscegenation, generates this virus—these microbes, these bacilli, which claim for their victims more than twenty-five per cent. of the dying.

Are there any races comparatively free from tuberculosis and all strumous affections? Wherever you see the purity of race maintained in civilized or barbarous countries there you see little or no tuberculosis and scrofula. Do these affections prevail among the Jews and other unmixed races to anything like the extent observed in countries overrun by immigrants of every race and producing crossed races without limit or regard to race affinities?

Broca mentions the assertion by other ethnologists "that the United States, where the Anglo-Saxon race is still predominant, but which is overrun by immigrants of various other races, is by that very circumstance threatened with decay, inasmuch as this continuous immigration may have the effect of producing a hybrid race containing the germ of disease, decay and future sterility."

There are serious men who have predicted from ethnologic causes the overthrow of the United States, just as Ezekiel predicted the ruin of Alexandria.

The difficulty in finding instances in the past of nations surviving such influences may excite faith in the prediction, in spite of our unexampled growth, that the fundamental facts as to the perpetuation of crossed races will ultimately prevail even in our own country.

In conclusion, I am fully conscious of the fragmentary nature and narrow scope of this paper. I have made no attempt to go into the literature upon this subject, with which indeed I am too imperfectly acquainted.

I have simply endeavored to set forth these crude ideas, which have been the outgrowth of my own observation. If they stimulate the profession to a livelier sense of the importance of looking back beyond the bacillus, and of teaching purity of race in

order to secure greater freedom from tuberculosis, less mortality, less crime, less idiocy and insanity, and greater longevity than are found among any race of hybrids, it will fulfil the object for which it was written.

THE OPERATIVE TREATMENT OF VENTRAL HERNIA RESULTING FROM ABDOMINAL SECTION.[1]

BY D. TOD GILLIAM, M.D.,
PROFESSOR OF OBSTETRICS AND GYNECOLOGY AT STARLING MEDICAL COLLEGE, COLUMBUS, OHIO.

VENTRAL HERNIA, succeeding abdominal section, differs from the ordinary forms of hernia in that there is no sac with a constricted neck. It forms a broad-based protrusion of the abdominal wall, and is the result of a stretching and separation of the abdominal parietes. The mischief commences in the line of incision, usually the linea alba, which, yielding to the pressure of the abdominal contents and the lateral traction of the abdominal muscles, bulges forward. This forms an entering wedge, and progressive thinning and separation of the fibers go hand-in-hand with increase of bulk. The bulwarks that prevent this occurrence, under natural conditions, are the triangulated arrangement of the superimposed fibers of three sets of muscles, ably reinforced in the middle line by the recti, to which may be added the fascia and the fibrous commissure of the linea alba.

The peritoneum proper, I think, offers little resistance to the intra-abdominal pressure, and yet I believe it plays an important rôle in the prevention and promotion of ventral hernia. In the natural state the parietal peritoneum offers a perfectly smooth, slippery surface to the visceral peritoneum, and this, in connection with the rotund shape of the abdomen, is a valuable safeguard against hernia.

There is no direct and continued impact of the viscera against the walls, for with every varying movement of the body, however slight, they glance and glide away from each other, thus ever shifting and equalizing the pressure. I will not recount the manner in which the different layers of muscle, with their fibers running in different directions, contribute to this end by insensible contractions, and how they reinforce each other in meeting the assaults from within.

Now, anything that roughens the peritoneum acts as a predisposing cause of hernia. Adhesions to the same membrane are of like import, though in the main conservative. The intra-abdominal pressure becomes concentrated and persistent, and the result is a final yielding of the parietes. Another factor is the cicatricial tissue in the line of incision. I am aware of the fact that some of the operations now in vogue for the radical cure of hernia are based upon the formation of a cicatricial plug at the site of hernial protrusion.

It is a very common belief that a tissue is resistant and stable in proportion to its density. This, however, I believe to be an error. Cicatricial tissue will not compare in point of endurance with healthy, natural tissues. It has not the vitality. It is not momentarily renewed and strengthened as they are. It is just in those cases in which suppuration and healing by granulation take place that we reap the harvest of herniæ after our abdominal work. Another factor, and one of the most important, is the retraction and contraction of the abdominal muscles. They continually draw away from the weakest point, enlarging the gap and still further weakening the vulnerable part. The woman with relaxed abdominal walls, of which the muscular tonus is diminished, is, according to my experience, much less susceptible to hernia than she of undiminished muscular vigor.

After the hernia is formed and the parietal resistance removed, the viscera become dislocated, with elongation of their ligamentous attachments and prolapse of the mesentery. The places previously occupied by the organs contract, and there is no more room for them in the cavity proper; they lack the support of their natural attachments. Thus by degrees everything becomes changed, and the difficulties multiply. For these reasons the operative treatment of ventral hernia must often be an unrequited task, and this probably accounts for the general apathy and paucity of literature on the subject.

In the light of the foregoing, the ideal treatment of ventral hernia of this form would be to enter the peritoneal cavity, break up adhesions, lop off redundancies, restore the healthy peritoneum, and so manage the superimposed structures as to bring them as nearly as possible into their natural state and relations, and secure healing by first intention to avoid the weakness of scar-tissue. In a large proportion of cases this is impracticable, and the difficulty is enhanced by the altered state of the abdominal cavity and its contents.

What we most need is an operation that will give a fair measure of success, and which is sufficiently simple and easy of execution to secure its general adoption. It should also be comparatively safe. The invasion of the peritoneal cavity, especially when adhesions exist, must therefore be avoided; for, aside from the extreme difficulty attending the section, when bowel and omentum are glued to the attenuated abdominal wall, rendered more difficult still by the flabbiness incidental to a hernial pouch, the length of time necessary to, and at times the im-

[1] Read in the Section of Obstetrics and Diseases of Women of the American Medical Association, at Detroit, June, 1892.

possibility of, liberating the adhesions, render the procedure extremely unsafe.

The next most desirable method would be to cut down to and deflect the fascia to one side of the median line, dissect up the muscular structures from the median line outward on both sides, interdigitate or overlap these from opposite sides, and suture them in their relative positions. The object of this method is to avoid the weakness and defects attendant on a direct line of union by interposing a series of muscular, fascial, and cutaneous structures between the cavity and the outer world on the median line.

This, while theoretically plausible, is practically impossible; for, it must be remembered, that even in the normal state it is next to impossible to curtail the abdominal cavity to such an extent as to allow the overlapping of muscles and fascia from opposite sides, and now, that the capacity of the cavity has been reduced, the difficulty is even greater. "Yes, but," it will be said, "there is a redundancy in the pouch that will easily admit of this." I think that on careful examination very little muscular structure will be found at this point, and such as may be found will be so attenuated, wide-meshed, and wanting in contractile properties as to be of little avail. The fascia might be of some benefit, but the skin is too extensile and wanting in elasticity to be of lasting service.

The technique that I have adopted, and which seems to me the most practical, the easiest of execution, the safest and the most lasting in its results, will be recognized as an old-time friend in a new garb. It simply consists in the denudation of an elliptical surface, the turning in of redundant tissue, and the union by suture, and, as an operation for cystocele, has been in use many years.

Before describing the operation in detail, however, it will be necessary to give the preliminary treatment. If the case be one of long standing, with prolapsed viscera and a contracted abdominal cavity, the patient will need a preparatory treatment of several weeks' duration. The object of this treatment is to restore, in a measure, the lost abdominal capacity and to strengthen, if possible, the visceral supports. The bowels must be assiduously attended to; the general health looked after; massage used to improve the muscular tonus, and the patient kept recumbent. At stated intervals, say once or twice a day, the patient is placed in the Trendelenburg position, to distend the upper abdomen and to restore the organs to their natural positions. The length of time that this position will be maintained will depend on the easy endurance of the patient. Flatulence, if it exists, should be combated by the proper remedies, of which turpentine is one of the best. For several days preceding the operation measures directed to securing asepsis should be resorted to, not only in the way of general baths, but the cutaneous surface over and around the hernial patch should receive the most painstaking care. In view of the exceeding difficulty attending this part of the work, on account of the lax and wrinkled condition of the skin, I have directed that the patient be placed on her feet during the scrubbing, in order that the skin might be put upon the stretch and the wrinkles effaced. The researches of Kelly have shown how extremely difficult it is to dislodge the germs that ensconce themselves between the layers of epithelium, and hence the extra care. As healing by first intention is the *sine qua non* to a successful issue, it will be seen that the preliminary cleansing process cannot be too rigid. All this having been attended to, and the utmost care being observed in the preparation of the instruments, appliances, and the persons of the operator and assistants, the case is ready.

Operation.—With a curved sound depress the pouch over the median line, carrying the instrument in toward the cavity, and with tenacula approximate the sides, being careful not to use traction, as there must be no tension. The line of contact will be found to be elliptical. This may be blazed, or marked out with iodine or ink. Now, with scissors and tenaculum, follow this around, laying bare the fascia and working toward the center, until an inch or more is exposed. This leaves an elliptical island surrounded by an elliptical furrow. It is well to freshen the outer margin of the skin of the island. If the area is not too large I am in the habit of denuding the whole. Bleeding vessels being secured, the blood and débris cleared away, and the parts washed with an antiseptic solution, a small rubber drainage-tube is slipped over the sound and the parts depressed as before. The tube must be long enough to project at either extremity. The use of the tube is sometimes dispensed with, especially if the entire surface has been pared. A continuous catgut suture is now run along the inner aspect of the denuded strip and made to include the skin-margin of the central island. A second and a third row are superimposed until the gap is closed and the parts brought into nice apposition. The probe is now withdrawn, leaving the drainage-tube in place. Aristol is sprinkled over the wound and a heavy layer of gauze over this.

Strips of rubber adhesive plaster, to which tapes have been attached, are now applied to the sides of the abdomen well down, and the tapes tied over the dressings in the median line. Over this is placed a thick layer of absorbent cotton, held in place by a four-tailed flannel bandage. The patient is put to bed and treated just as after abdominal section, the object being to prevent vomiting and the accumulation of intestinal flatus.

ORIGINAL LECTURE.

ENDOCARDITIS—ANEMIA—AORTIC STENOSIS —ENLARGED SPLEEN.

BY JOSEPH M. PATTON, M.D.,
PROFESSOR OF INTERNAL MEDICINE IN THE CHICAGO POLYCLINIC.

ENDOCARDITIS.

GENTLEMEN: This woman is twenty-eight years old and married. She came to this clinic about a year ago, complaining of pain in the cardiac region, some dyspnea, and slight cough. She had a rapid, irregular pulse; the heart's action was excited and forcible. She had no elevation of temperature. There was slight edema about the ankles. The urine was scanty and high-colored; it had a specific gravity of about 1028, and contained no albumin and no casts. At that time she presented a faint mitral regurgitant murmur, and a diagnosis was made of endocarditis affecting the mitral valve. She was placed on sodium bromide and small doses of tincture of opium; she was also given some potassium acetate. Under this treatment the pain in the cardiac region disappeared, the pulse became more regular, and the edema about the ankles disappeared. She was then placed on tonic treatment and has continued to improve until the present time. She gave us a rheumatic history, having had rheumatism at various times in early life; during the present winter she has had rheumatism of various sets of muscles, for which she has had sodium salicylate. To-day you will notice that her pulse is regular and a little forcible; the impulse of the heart is a little to the left and very slightly displaced downward. She does not complain of pain at the present time or of cough, and says that her heart gives her no trouble. The forcible action of the heart at present is probably due to excitement in coming before the class. Over the mitral area you will notice a very slight prolongation of the first sound, which is carried indistinctly toward the left. The endocarditis from which she was suffering when she first appeared in this clinic has subsided, leaving of course some trouble with the mitral valve, which is the cause of the murmur we hear to-day. The right side of the heart has compensated fully for this condition, so that she does not suffer at all from trouble with her heart. We will again place her on sodium salicylate and small doses of potassium iodide. The latter is given both as an alterative and as a direct cardiac tonic. According to recent investigations potassium iodide has a twofold therapeutic action: it causes temporary contraction of the small vessels, followed by dilatation, involving the coronary circulation as well as the general circulation. We may thus expect to improve the nutrition of the heart-muscle by increasing the amount of blood furnished to the organ itself.

ANEMIA WITH ENDOCARDIAL MURMURS.

This young woman is nineteen years old and is a sister of the one of whom we have just been speaking. She came to the clinic about three months ago complaining of amenorrhea. She was given some uterine tonic at that time, which stimulated her menstrual function, and she menstruated regularly the following month. She comes back to-day saying that she has not menstruated during the last two months. You will notice that her skin is pale and sallow; the mucous membranes are somewhat blanched; the cornea is unusually clear and white. The skin does not have the greenish-yellow hue of chlorosis; nor are the mucous membranes as white as they appear in that disease. The patient says that her appetite is not good; her bowels are regular; she does not suffer from headache, but occasionally has slight spells of dizziness. Her pulse is rapid, rather small and compressible. On looking at her chest the action of the heart is seen to be rapid and somewhat forcible, probably as a result of excitement. The apex-beat is in the normal situation. On listening to her heart you will observe a soft, blowing systolic murmur, heard over an area bounded by the upper border of the third rib above, the lower border of the fourth interspace below, the left edge of the sternum on the right, and a parallel line on the left about two inches from the edge of the sternum. This murmur is heard best at the base of the heart, but can be readily distinguished all over the area described. You will also hear along the course of the subclavian vessels a loud blowing systolic murmur, much harsher than the one heard over the heart. This murmur is heard only on deep inspiration, and is heard as long as the lung is held fully expanded, disappearing with the beginning of expiration. You can also hear the venous hum, the so-called *bruit de diable* of the French, over the jugular vein, although it is not very well marked in this case.

Now, these murmurs are hemic in character, and due to the watery condition of the blood. This is a case of simple anemia. Anemia is often found in young girls at about the age of puberty. Among the Bohemians and Poles especially we often find well-marked cases of chlorosis at this period, and they are nearly always associated with amenorrhea. Among the Americans we find more cases of simple anemia, and they may be associated with amenorrhea or menorrhagia. We find then, in this case, sufficient reason for the amenorrhea. These various hemic murmurs, both endocardial and vascular, which occur in these conditions, are valuable as confirmatory evidence of an anemic condition. We will often hear a vascular murmur when no cardiac murmur can be detected, and the vascular murmurs, that is, those produced in the subclavian vessels, afford a more reliable diagnostic indication of the watery condition of the blood than does the venous hum in the jugular. These murmurs in the subclavian vessels have been supposed to be due to pleuritic adhesions, making traction on the costal pleura. I do not think that this is the real cause. They are probably due to pressure on the subclavian vessels by the expanded lung, which changes the anatomic relations of the part, making some portion of the artery narrower in caliber, because, when present in cases in which the expansion of the two apices is not equal, they will be found best marked on that side that shows best expansion, and not on that side on which we might have reason to suppose that there could be pleuritic adhesions. The cardiac murmur in this case is one of the most distinct endocardial murmurs that you may expect to hear.

The diagnosis from organic murmurs is important, because when a hemic murmur exists in young persons that have presented evidences of rheumatism, such as those transient pains commonly called "growing pains,"

and often associated in early life with a rapid, forcible, and irritable heart, they may readily be mistaken as rheumatic.

Intra-cardiac hemic murmurs are always systolic and softer than cardiac murmurs of organic origin, with the exception of occasional cases of mitral regurgitant murmurs. They are heard loudest at the base of the heart, over only the cardiac area, and are not transmitted as organic murmurs may be transmitted. The hemic murmur, for instance, is heard plainly to the left of the sternum; it is not transmitted, although it may be distinguished as far dowa as the point of apex-contact, but not plainly. It is not heard at all outside of the mitral area or to the right of the sternum.

Now, the treatment of this case must necessarily be directed to the improvement of the condition of the blood, the specific gravity of which is lessened and the hemoglobin diminished; the corpuscles are smaller, and the same number of corpuscles will occupy a much smaller space than they would in healthy blood. When this condition results from want of corpuscular development, it is termed anematosis. When due to degeneration of the corpuscles, it is called hemophthisis. The blood-mass may be diminished; to this the term oligemia is applied. The best medicines to improve the condition of the blood are the various iron tonics, and the most efficient is the fresh carbonate of iron. This is made by using equal proportions of iron sulphate and pure potassium carbonate with a little sugar and enough acacia to make a mass. It is preferable to the sugar-coated pill. A fifth of a grain of nux vomica may be added to this pill to improve the innervation of the vasomotor system, which is always at fault, as the vascular tension is always low in cases of this kind. As much of this medicine should be administered as the patient can take. Four or five grains should be given after every meal; the dose may be increased if the stomach bears it well. For the gastric trouble that is often associated with this condition you may give a few grains of sodium bromide with a little pepsin, with some powdered charcoal if there is fermentation and eructations of gas. Constipation will be nicely relieved by the employment of cascara sagrada two or three times a day.

We will place this young woman on this line of treatment, and as soon as her nutrition is improved we can confidently predict that her menstruation will become regular. In order to stimulate the menstrual function, it is well to administer some such remedy as she was given before, at about the time that she would expect to menstruate—any reliable preparation of viburnum.

SLIGHT AORTIC STENOSIS OF LONG STANDING, FOLLOWED BY OVERSTRAIN OF THE HEART AND DILATATION.

This young woman is twenty-three years old and married. She states that she had rheumatism when she was ten years old, but not since that time. She comes to the clinic on account of a cough that she has had for two months. She also says that she has recently had slight pains in the region of her heart, with some palpitation, and occasionally slight dizziness. On examination of her lungs we find nothing to account for her cough. Her heart is beating rapidly. The action is forcible; the area of cardiac impulse is increased. On percussion, the area of dulness extends to the nipple line; it is also displaced downward about half an inch. On auscultation in the mitral area we hear a faint, soft systolic murmur transmitted only a short distance to the left. Over the aortic valves there is a slight prolongation of the first sound, indicating that the aortic valves are somewhat stenotic. Now, this stenosis at the aortic valve is probably of long standing and due to the rheumatism that she had in early life. This condition would account for the moderate hypertrophy of the left ventricle and for the slight displacement of the heart downward. At the present time, however, we find the left ventricle dilated. The dilatation is relatively greater than the slight hypertrophy that has taken place; we must seek a cause for this dilatation. It is evident that the dilatation is not the result of degeneration of the heart-muscle, because the muscle, as you will observe by the character of the heart's action and the quality of the first sound, is in good condition.

The patient tells us that she is a dancer by profession and has followed this occupation for a number of years, for several hours every day, and that lately some of the figure-dancing has been especially hard, and that she has noticed that it was more difficult for her to do than formerly. This would explain the cause of the dilatation. Given a heart slightly hypertrophied on account of moderate aortic stenosis, we have a condition in which compensation has been effected, and which would probably have given her no trouble if she had not been subjected to overstrain; but the violent action of the heart necessary in the active exercise of dancing raised the intra-ventricular pressure to such an extent that the cavities of the heart were dilated, the mitral ring was slightly stretched, and she has a slight relative mitral regurgitation, which explains the production of the mitral murmur now present. It also explains why we should have a dilated ventricle with so good a heart-muscle. The condition would come under the head of idiopathic enlargement of the heart as described by Fraentzel. Fraentzel, Leyden, and Schott have described cases of cardiac dilatation resulting from acute overstrain of the heart.

Now, in treating this case, the first thing to do is to relieve the heart of any such strain. The woman must stop her dancing. If she does this the condition will diminish of itself, the dilatation will subside, and the heart may be able to perform all the labor required of it. To quiet the action of the heart and the nervous arhythmia present in this case we will give her ten grains of sodium bromide, with half a drop of tincture of aconite, three or four times a day. She will also be given some general tonics; her diet will be regulated; and if she will give up her dancing we can safely assure her improvement.

This young woman is also a dancer. For the past three or four months she has been troubled with palpitation of the heart, some dyspnea, and some dizziness. On examination we find the action of the heart more forcible than in the other patient. The limit of dulness is not so much displaced to the left, and it is also very slightly displaced downward. There are no abnormal valvular sounds to be heard in this case, and the signs are simply those of moderate hypertrophy on the left side. This hypertrophy in so young a girl, in the ab-

sence of any valvular lesions or any abnormal condition of the vascular tension, in the absence of any evidence of disease of the kidneys or any of the organs, can only be explained by the nature of her work. The enlargement of the heart, due to the strain of dancing, in this case is one simply of hypertrophy. In the other there was an already constricting valve at the aortic orifice which modified the conditions, and therefore we would have dilatation under the same conditions as we get simple hypertrophy in this instance.

These cases are interesting as showing the abnormal conditions of the heart that may devolop simply as a result of overstrain.

This girl should also be made to change her occupation. She should be placed on the same treatment as the other case, and although one is a case of hypertrophy, and the other one of combined hypertrophy and dilatation, the treatment would be the same in both instances, because the heart-muscle is good and we have virtually the same conditions to counteract.

ENLARGED SPLEEN.

This man is forty years old and a farm-laborer by occupation. He appeared at the clinic about three months ago in substantially the same condition as you see him now, presenting no history of interest, except that of enlargement of the abdomen. He had never been sick in his life, has never had any form of malarial fever, and knows of no reason why his abdomen should have enlarged in this way.

On looking at him you will observe an enlargement on the left side of the abdomen, occupying the left hypochondrium, extending down into the left inguinal region and over to the right of the umbilicus. On palpation you find this region filled with a tumor that is hard, smooth, doughy; it extends from about the ninth rib down to within two inches of the pubes and more than an inch to the right of the navel. As you place him on his back and draw up the knees, you find that you can palpate a large tumor. It is sharply rounded and shelving; the point of the tumor is directed downward and toward the right inguinal region. To the right of and just above the umbilicus you will find a V-shaped notch in the abdomen, which tells you at once that you have a spleen to deal with, this being the hilus of the organ and being characteristic of the splenic outline.

Now, you will remember that the spleen is enlarged in various conditions. It may be enlarged in acute exanthematous diseases; it may be enlarged in malarial fevers; you may have a chronic hypertrophy of the spleen as a result of malarial disease; you may have it enlarged from cysts, hydatids, carcinoma, tuberculosis, and other conditions. This evidently belongs to the chronic enlargements of the spleen, such as we find resulting from chronic malarial poisoning or from leukocythemia. The differential diagnosis of these conditions can only be made by examination of the blood. We place a specimen of this man's blood under the microscope and you will readily recognize, without any special effort at accurate measurement of the number of corpuscles, that the white corpuscles are relatively greatly increased in number. You notice that they are large and granular and that their outline is not very distinct. This tells us that we have a case of leukocythemia.

You will remember that there are three principal varieties of leukocythemia—the splenic form, of which this is an instance, and in which the enlargement of the spleen is the main symptom; then we have the lymphatic form, in which the lymphatic glands in the various parts of the body are enlarged, with or without marked enlargement of the spleen; lastly, we have the so-called myelogenic form, in which the marrow of the long bones is involved, being transformed into a puruloid condition and increased in quantity.

Leukocythemia may present a variety of symptoms. There may be fever, irregular chills, disturbance of digestion, diarrhea alternating with constipation, petechial eruptions all over the body, hemorrhages into the serous cavities, such as the tunica vaginalis testis, the peritoneum, the pericardium, pleura, or the arachnoid cavities of the brain. There is also a liability to cerebral hemorrhage, from degeneration of the coats of the vessels. These various symptoms are more likely to be present in the lymphatic and myelogenic forms of leukocythemia than in the splenic form.

The duration of the disease is estimated at from three months to three years. The splenic variety, when presenting no fever or no digestive disturbance, may last much longer. Patients may die suddenly from cerebral hemorrhage.

The treatment is not satisfactory. We have as yet no recoveries of this condition recorded. Transfusions of blood have been partially successful. Extirpation of the spleen has totally failed. Intra-parenchymatous injections of ergot, carbolic acid, sclerotinic acid, and other substances have been largely practised by Mosler and others, with the effect of causing partial contraction of the spleen, but no cures have been effected.

In this case we have been following the established treatment of iron, arsenic, and quinine. The man has been taking ten drops of iron citro-muriate, five drops of solution of potassium arseniate, and five grains of quinine sulphate, three times a day. His spleen is smaller now than when he first presented himself at the clinic. He tells us that he can now eat a comfortable meal without any disturbance of his stomach, which he could not do previously on account of the pressure on his stomach from the enlarged spleen; then, too, the tension of the abdominal walls is not as great and the tumor can be more readily palpated than at that time. Without promising much in this instance, we feel warranted in continuing this line of treatment, as the man is more comfortable and the spleen somewhat smaller in size; but the prognosis is still serious. These cases sometimes improve temporarily, and die suddenly from cerebral hemorrhage or some unknown cause.

CLINICAL MEMORANDA.

GENERAL RESPIRATORY TUBERCULOSIS:

Pulmonary, Laryngeal, Nasal.

BY CHARLES P. GRAYSON, M.D.,

ASSISTANT PHYSICIAN, DEPARTMENT OF DISEASES OF THE THROAT AND NOSE, HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

THE interest in the case herewith reported lies not only in the uncommonly wide distribution of the disease, but in certain methods of treatment adopted, and their

results. The lungs were the parts primarily and most extensively involved, but it was for the consecutive laryngeal and nasal lesions that the patient came under the partial supervision of the Throat Department, and it is of these latter that I shall speak with the greater detail.

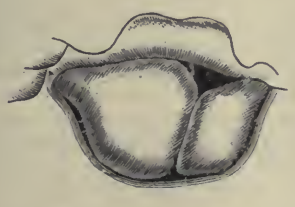
To dispose as briefly as possible of the family and previous personal history, I quote from the notes of the resident, Dr. Furness, who kindly permits me to do so:

"George McV., aged thirty-two years; machinist; English. Both parents, a brother and a sister, all died of phthisis. Until within a year prior to his admission to hospital, a fairly healthy man. At that time a cough, which had troubled him more or less for some months, became suddenly aggravated. Flesh and strength were rapidly lost and the voice became weak and hoarse. Six months ago, external swelling of the throat appeared; the voice was entirely lost, and swallowing became both difficult and painful." Physical examination disclosed extensive disease of both lungs, further advanced in the right than in the left, the right upper lobe containing cavities and the lower lobes showing numerous areas of softening.

The patient's first visit to the Throat Department was made December 19th. He was brought down from the ward in a wheel-chair and presented a most pitiful spectacle. Emaciation was extreme. Cough was frequent and painful, quite aphonic, and only slightly productive. Voice was extinct. Aside from his general appearance, the most prominent objective symptom was dyspnea. Loud inspiratory stridor was present, all the accessory respiratory muscles being in play, and the nasal alæ widely dilated. Externally, the prominence of the larynx was increased to almost double its normal size, and seemed even larger from the advanced wasting of the neighboring cervical tissues. There were, in addition, some redness and edema of the overlying skin, with considerable tenderness on pressure.

Laryngoscopic examination. The appearance of the epiglottis departed but slightly from the normal. There was moderate swelling, due apparently to simple edema, and a number of dilated veins coursed over the anterior surface. Below this, however, the larynx presented a picture of advanced tuberculous disease, from which death by asphyxia seemed imminent. The accompanying sketch may, perhaps, convey a clearer idea of its menacing condition than could a verbal description.

Fig. 1.



It will be seen how very small an aperture remained for purposes of respiration. The whole infiltrated mass was immovable, forced inspiration, or attempted phonation producing no perceptible alteration in the mirrored image. As to coloring, the typical grayish pallor of tuberculous disease predominated, but it was splashed here and there by patches of catarrhal hyperemia. All of the mucous membrane in sight was still intact, but the absent voice, the agony attending deglutition, and the degree of general swelling, spoke but too plainly of active destruction going on below the parts shown in the glass. The previously mentioned redness and edema of the skin, with the marked tenderness on pressure, were suggestive of implication of the cartilages.

Above the larynx the pharyngeal and oral mucous membranes were characteristically anemic.

The nose. On both sides anterior rhinoscopy disclosed the same anemic condition of the lining mucosa as was present in the lower portions of the respiratory tract. In addition, however, on the left side, just within the margin of the vestibule, an ulcer was discovered on the septum. This lesion corresponded closely in appearance with the classical descriptions of the tuberculous ulcer in this region. There was no encircling inflammatory areola; the edges were flush with the contiguous tissue and passed into a slightly depressed, caseating center. The ulcer seemed entirely non-secreting, only a few particles of necrotic tissue being found upon its surface. In shape it was irregularly oval, its longer diameter measuring 11 mm.

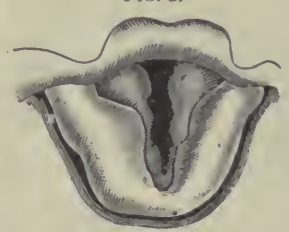
The management of the case, so far as it related to the pulmonary disease and the patient's general condition, was in other hands, and will not be considered here. That portion of the treatment, however, directed specially to the lesions involving the throat and nose, claims notice because of its having included the use of mercuric chloride in watery solution as an agent with which to check the accompanying destructive ulceration in these regions.

At the time when local treatment was first instituted, the larynx presented in an eminent degree the condition termed by Gottstein "pseudo-edema"—the enormous swelling being due, not to a simple inflammatory exudation into the meshes of the submucosa, but to the specific tuberculous infiltration of the tissues generally. The scattered superficial catarrh, no doubt, played a minor part in adding to the swelling, and constricting still further the already dangerously diminished space for the entrance of air, and it was to the subjugation of this that the earlier treatment was directed. This consisted of but little more than routine measures, viz., the external application of ice-water compresses, inhalations every few hours of steam medicated with compound tincture of benzoin, thorough cleansing of the larynx once daily by the use of a mild alkaline spray, followed by spraying with a 4 per cent. solution of cocaine, and this again by generous insufflations of a powder composed of iodoform, bismuth, tannic acid, and acacia. It is scarcely necessary to add that the diet during this time was entirely liquid and bland.

By the close of the first week there was much cause for satisfaction. The simple catarrh had subsided, and with it enough of the swelling to greatly relieve the dyspnea and to markedly facilitate expectoration. Nutrition was improved, considerable strength regained, and the patient abandoned his wheel-chair and came for his daily treatment unassisted. At this point, an intervening Sunday causing the lapse of forty-eight instead of twenty-four hours without treatment, seemed to give the invading bacilli the opportunity of resuming active hostilities. The morning of December 28th found the laryngeal

condition almost, if not quite, as grave as at the first examination. The previous treatment was renewed and continued without change, but the examination of the next day showed that the progress of the disease was not again to be arrested without the aid of some powerful ally. Small superficial erosions on the left ary-epiglottic fold heralded the commencement of general disintegration of the infiltrated tissues. Additional erosions soon appeared on the right fold also, and on both sides these rapidly coalesced, deepened, and passed into active ulceration. In the face of this exhibition of weakness upon the part of iodoform, it was determined to substitute for it a solution of mercuric chloride. The strength first employed was 1 : 500. As a sort of control-experiment this was applied for the first two days to one side only, the right, while the iodoform was continued upon the left. This period, brief as it was, proved quite long enough to exhibit a marked difference in the behavior of the two ulcerating folds under the two methods of treatment. The right had undergone easily-perceptible improvement by the end of the second day, while the ulceration on the left side seemed to have been quite unaffected in its progress by the daily coating of iodoform. Subsequently, therefore, the bichloride solution was applied to both sides. The cotton-wool tufts used for this purpose were made to carry a just sufficient quantity of the medicament and no more. Thus the action of the solution was carefully limited to the cocainized ulcerations, and no excess was allowed to jeopardize the integrity of still intact membrane or to expose the patient to the risk of the toxic effects of the drug. For almost two weeks the condition of the larynx underwent steady improvement. Destruction was checked, vigorous granulations made their appearance, and as these underwent transformation into cicatricial tissue, considerable contraction of the swollen folds occurred, with coincident widening of the respiratory aperture and proportionately diminished dyspnea. At this time the disease-process seeming so well under control, another Sunday was allowed to pass without treatment. Before the day was over, however, the patient, through some carelessness of his own, became chilled, the weakened throat felt the effects of the shock most keenly, and the ensuing morning found us con-

FIG. 2.



fronted by a second relapse. Appearances were again so menacing that, rather than risk having all that had been accomplished quickly undone, the strength of the bichloride solution was doubled, making it 1 : 250. Once more it proved wholly efficient, the threatened recommencement of disintegration was averted, and from this time until the patient's death the larynx was kept entirely neutral so far as its exerting any influence in hastening that result was concerned. On February 4th, three days previously to death, this second sketch was made. Comparison with Fig. 1 will demonstrate with sufficient clearness, it is hoped, what the treatment had accomplished.

Autopsy. The larynx being removed, examination revealed the following condition: In spite of post-mortem shrinkage, it was, as a whole, much larger than normal. But little remained of the vocal bands—these, together with the lower thirds of the ventricular bands, having been almost completely destroyed. The upper portions of the ventricular bands were merged above into the thickened ary-epiglottic folds, and these latter bore upon their upper surfaces smooth, well-organized cicatrices, free from vegetative proliferations, and showing but slight traces of the recent active ulceration. Death was due to asthenia, the advanced destruction of the lungs found fully confirming the results of physical examination.

A few words in conclusion as to the nasal lesion. The reported cases of genuine tuberculous ulceration of the nasal cavities are comparatively few (under thirty) in number. I much regret that, no microscopic examination of the contents of this ulcer having been made, the diagnosis may be fairly questioned. If, however, in connection with the characteristic local appearances present, the case be considered in its entirety, together with the fact that all of the other probable or possible causes of such ulceration could be definitely excluded, I think that but little doubt can reasonably be entertained as to its tuberculous nature.

Regarding its treatment: Its location made it so easy of access that the galvano-cautery promptly suggested itself as the speediest means for its eradication. This is a measure that has been successfully adopted and warmly advocated by several Continental authorities. During the first week, however, the patient's general condition forbade an immediate resort to this measure, and the same local applications were made here as to the larynx. The result was largely negative. The ulcer became cleaner and, in so far, improved in appearance, but at the end of ten days it had not undergone the least contraction, and no disposition to the formation of healthy granulations was manifest. Simultaneously with the first use of mercuric chloride to the larynx, it was applied here. The ulcer being first thoroughly curetted, the 1 : 500 solution was pressed firmly into the resulting excavation. Healing was much more prompt than in the more inferiorly situated disease, the comparatively sheltered position of this lesion and its freedom from the constant disturbance to which the larynx was subjected, enabling it to outstrip the latter in their common course toward cure.

A CALCULUS IN WHARTON'S DUCT.

BY J. THORINGTON, M.D.,
OF PHILADELPHIA.

G. S. A., a shoemaker, thirty-two years old, a German by birth, presented himself at the Throat Clinic of Jefferson Medical College Hospital, complaining of "sore-mouth" that had existed for two years.

Two years previously, while at work, he was, without apparent cause, seized with acute pain in the floor of the

mouth, to the right side of the tongue; this pain gradually extended to the right side of the face and neck, becoming so severe after three days that he could not sleep, and the parts became so swollen that it was impossible to swallow solid food. In this condition he sought medical aid, and after two days' use of gargles and washes, a thick, clear fluid began to flow from the mouth, and convalescence was rapid, except that, ever since this attack, he has had a daily paroxysm of pain at the original focus, coming on as a rule at about dinner-time.

Examination revealed a prominence on the floor of the mouth, between the tongue and the teeth of the right side; this prominence was not sufficient, however, to raise the tongue, and was only noticed when the patient elevated or retracted this organ.

At about a quarter of an inch to the right of the middle of the frenum linguæ, a small whitish opening could be seen, slightly elevated above the mucous membrane, the patient explaining and demonstrating that through this opening, by digital pressure upward, inward, and forward to the inside of the ramus of the jaw, a fine stream of clear fluid could be ejected through the open mouth, to the left, a distance of a foot or more. It was in this way that the patient had been getting relief from his daily attack of pain during the preceding two years.

On palpation with the right index finger in the mouth, and the fingers of the left hand under the jaw, a hard, elongated tumor, painful on pressure, could be felt, extending from within a quarter of an inch of the frenum on the right side, back between the teeth and the tongue, a distance of an inch. This tumor was larger anteriorly and diminished in size posteriorly.

Probing the opening previously mentioned, a hard grating substance could be distinctly felt.

After applying a 4 per cent. solution of cocaine, an incision half an inch in length was made over the tumor, extending backward from the point of opening. A calculus immediately presented, and with the aid of forceps was extracted. A probe was then introduced into the wound without any difficulty, passed backward, slightly downward and outward a distance of two and a half inches; no other calculi being detected in the duct or gland, the cavity was cleansed with a ten-volume solution of hydrogen dioxide, then dried with absorbent cotton, and finally swabbed out with the following solution:

℞.—Potassii iodid.	gr. xxx.
Tinct. iodi	f℥j.
Glycerin.	f℥ij.
Aq. dest. . . . . q. s.	f℥jss.

This solution was applied daily for three days, and the wound was permitted to heal.

A week later the patient reported that he was well, and inspection showed the wound to have closed. The surface of the calculus was rough. The mass weighed twenty-one grains. It measured an inch in length, an inch in circumference at the larger, and three-eighths of an inch at the smaller extremity. The general shape of the calculus was not unlike that of a large date-seed.

Careful analysis showed the calculus to be composed of carbonate and phosphate of lime.

In presenting this case I wish especially to note:

1st. The history of sudden onset, which suggests the strong probability of the nucleus of this calculus having its origin in the submaxillary gland, and being washed forward by the salivary secretion, and as not having its origin in the duct; and

2d. The importance at all times of a careful examination. This patient before coming to the clinic had visited three physicians; two told him it was "nothing," and the third said he had a ranula; none, however, had made a digital examination or probed the opening.

1630 Arch Street.

MEDICAL PROGRESS.

Proctectomy for Carcinoma of the Rectum. — Brown (*Lancet*, 1892, 3588, p. 1235) reports the case of a robust, healthy-looking man, fifty-two years old, who presented symptoms of carcinoma of the rectum, and was losing much blood with every movement of the bowel. The growth was within reach of examination, but too high to allow of an ordinary proctectomy. The bowel was freely movable within the pelvis, and the finger could be passed beyond the disease. Left lumbar colotomy was performed, and five weeks later, the artificial anus being well established and acting freely, the lower segment of the intestine (between the opening in the colon and the anus) was twice daily for two days thoroughly washed with large quantities of a solution of carbolic acid, 1:80, until the escaping fluid was free from fecal taint. A silver catheter was passed into the bladder and held in position throughout the whole of the subsequent operation. The patient was then turned well over on the right side, and the thighs were flexed on the abdomen. A square flap, four inches in length and four in width, including all of the soft tissues, was raised from the posterior surface of the sacrum and turned upward, the free edge being two inches above the anus and the attached margin being opposite the third segment of the sacrum. The sacrum was then sawn transversely at the level of its fourth segment, the lateral attachments below, as far as the tip of the coccyx, severed, and this bone "flap" turned downward. The hemorrhage was free, but was controlled by "clip" forceps and sponge-pressure, a few of the larger vessels being tied. A finger was next introduced through the anus, well up into the rectum, and the gut gradually freed from its attachments by means of scissors. On attempting to draw the bowel out of the wound it was found that the disease extended higher than the cut edge of the sacrum, so that an additional three-fourths of an inch of bone was removed. The rectum was then divided above the internal sphincter, drawn out of the wound, and its posterior wall slit up beyond the limits of the growth. The bowel was now seized with large pedicle-forceps above the level of the growth and cut away with scissors, the line of removal being half an inch above the upper limit of the disease. The free extremity of the rectum was stitched in the upper right angle of the wound, and plugged with a large sponge. The wound was freely irrigated and filled with iodoform-gauze. The sacrum was then replaced, and the skin-flap turned down and secured by sutures. Free drainage was provided for. The wound was dressed with dry wool, and firm pressure was applied by means of a flannel roller. There was little shock. Apparently the peritoneal cavity had not been opened. A few days

after the operation the opening in the colon ceased to act, in consequence of the disappearance of the "spur" from traction on the bowel. As a result, fecal matter passed into the rectum, the wound became foul, and symptoms of septic intoxication appeared. The wound in the bowel was reopened, and the colon drawn out and divided. A catheter had to be employed as long as the patient was kept on his side. He passed urine without assistance as soon as he got out of bed. His general health was well maintained, and he suffered but little pain.

Nervous Hepatic Colic.—At the recent Congress for Internal Medicine held at Leipzig, FÜRBRINGER (*Suppl. Centralbl. f. klin. Medicin*, No. 25, 1892, p. 46) defines the characteristics of nervous hepatic colic. The attack closely simulates that of calculous colic, but the pain is most intense in the region of the liver. Nervous hepatic colic is a symptom of irritable weakness of the nervous system, and occurs especially in young, neurasthenic, and hysterical patients, often in association with other visceral neuralgias, such as pleurodynia, heart-pain, nephralgia, oöphoralgia. At times the knee-jerk is greatly exaggerated. The exciting factor in an attack is usually not apparent, and is rarely constituted by errors in diet, over-activity, anger, menstruation. The attacks frequently present a certain periodicity of recurrence. Icterus and swelling of the liver are wanting. Tenderness over the liver is always present. Although the affection may last for many years, it never leads to inflammatory conditions. The best therapeutic results are to be obtained by anti-neurasthenic treatment. Nervous hepatic colic may be associated with peritoneal adhesions of the liver to adjacent organs (usually in association with cholelithiasis).

Foreign Body in the Air-Passages for Five Months.—WILSON (*Glasgow Medical Journal*, July, 1892, p. 24.) has reported the case of a man, twenty-eight years old, in which a whistle, made of a circular piece of tin, perforated at the center and folded on itself, measuring at its base one and a half inches, and transversely three-quarters of an inch, was inspired into the trachea. Respiration was somewhat obstructed, and a peculiar metallic wheeze was heard on sudden expiration. Examination, however, failed to detect the situation of the foreign body. For five months the man suffered comparatively little inconvenience. There was dyspnea on exertion, and occasionally a sense of discomfort at the level of the upper portion of the sternum. On cough, the body could be felt to move. Sleep was disturbed by a sense of fear. One morning the man awoke with a tickling sensation in the throat, and on coughing the whistle was ejected.

THERAPEUTIC NOTES.

Trional and Tetronal.—As the result of a considerable experience at the psychiatric clinic at Jena, SCHAEFER (*Berliner klin. Wochenschr.*, No. 29, 1892, p. 724), concludes that trional and tetronal possess a hypnotic and sedative influence, tetronal being the more active sedative. The therapeutic effects appear in ten or twenty minutes after administration. Trional is indicated as a safe and promptly-acting hypnotic in cases of insomnia, of the various forms of neurasthenia, of functional psychoses and of organic disease of the brain. It fails in cases of morphinism or cocainism, or in which physical pain is a prominent symptom. Tetronal is indicated in cases of psychoses in which motor unrest of moderate degree prevents sleep. Neither is indicated as a sedative in cases of marked motor and mental excitement. From fifteen to thirty grains constitute an active dose; single doses of forty-five and sixty grains and daily doses of from ninety grains to two drams may safely be given. The drug is best given at bedtime, dissolved in milk or in wine. Other than slight irritation of the stomach and intestines, no bad effects were observed. Secondary manifestations were observed in a small number of cases. No unpleasant symptoms attended the withdrawal of the remedy after it had been given for some time; neither was a tolerance to the drug established.

Resuscitation after Drowning.—At a meeting of the French Academy of Medicine, LABORDE (*Münchener medicin. Wochenschrift*, 1892, No. 28, p. 501) reported the resuscitation from drowning of two cases by separating the jaws and alternately strongly drawing the tongue forward and pushing it backward. The strong traction on the root of the tongue exerts a reflex influence upon the respiratory apparatus, and may be made to conform with the respiratory rhythm.

For Scabies.—

Saponis viridis } . . . ää ℥j.
Adipis }
M. et ft. ung.
S.—Apply topically. HEBRA.

Strontium Bromide for Vomiting.—CORONEDI (*Practitioner*, July, 1892, p. 24) recommends the employment of strontium bromide for the relief of vomiting of nervous, or of gastric origin, or dependent upon pregnancy, and reports a number of illustrative cases. He prefers to give the drug in solid form, because of its deliquescence, in doses of fifteen grains, kept in tightly-corked vials, twice or four times a day.

For Parenchymatous Keratitis and Corneal Opacities.—

Creasote for Scrophulosis.—Based upon the result of his experience, SOMMERBRODT (*Berliner. klin. Wochenschr.*, No. 26, 1892, p. 641) renews his original recommendation of the employment of creasote in the treatment of scrophulosis. In children, the initial dose may be a drop or two, gradually increased, and always given after meals.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,

INVOLUNTARY NEWSPAPER DOCTORS.

NOT every man whose name and doings get into the newspapers is a sneak advertiser. A reporter may slip into the clinical amphitheater or be brought thither by an unwise student-friend. He will describe what he sees and mention the name of the teacher whose work he has witnessed. But the report will indicate its source by its inaccuracies and its curious and *naïve* phraseology, just as the dictated report betrays its source by accurate technical terminology. Then, again, the personal character of some men is sufficient evidence that accidental newspaper notice is not of their seeking.

A distinguished teacher of this city, a member of the faculty of a prominent college, lately sent us a clipping for our scrap-book, containing a report of an operation done by him at the college clinic. The accompanying letter assured us that the notice was extremely distasteful to him. This assurance was entirely unnecessary. In the first place, we knew the man, as the community and the profession know and honor him. It is a simple impossibility to connect his name with the shadow of a shade of unworthy suspicion. In the second place, the terminology of the report was unmistakably and ludicrously that of the reporter; it was graphic in its very blunders. In the third place, the few lines in which the story of a rare and really great exhibition of surgical skill and daring was told, the absence of other allusion to the operator than his mere name, and the prominence given to the names of assistants, formed a striking contrast to the columns of detail concerning patient, operation, and operator which the true and tried newspaper doctor would have had inserted.

We have lately learned of an even more annoying experience that happened to a member of the same faculty. This gentleman was invited by a classmate to a consultation in a neighboring city. To his extreme disgust he soon after received a number of newspaper clippings stating that "Professor ——— had been in the city in consultation with Drs. ——— and ———, whose advertisements would be found in the adjoining columns."

The question at once arises, How is one to guard against such occurrences? It is impossible. But the whole tenor of one's life and conduct must be such that his character is an immediate proof that he has had no part in the newspaper publication. We have quoted instances in which well-earned character does furnish such proof. How many could we not quote, in which character, equally well-earned, proves just the opposite?

THE "PACIFIC MEDICAL JOURNAL" AND THE QUACKS.

THE *Pacific Medical Journal* is to be congratulated on "the enemies it has made." It has bravely spoken the truth concerning the official action of the State Board of Medical Examiners of California; and concerning the shameless quackery of certain medical men of San Francisco, some of whom, it seems, are members of the County Medical Society and State Medical Society, and some of whom occupy prominent official positions in the public service.

We thought that certain "eminent practitioners," residing less than a thousand miles from the marble tower that is to be topped by a statue of WILLIAM PENN, understood to perfection the art of "working the newspaper racket," but we confess that the methods of their brethren of the Pacific Coast are, if less sly, apparently better calculated to attract the nimble dollar. The *Evening Telegraph*, of this city, has frequently asked why physicians should not be allowed to openly advertise, and perhaps the experience of that journal warrants the question. It would certainly be more decent and more business-

like on the part of medical men to use the advertising columns of newspapers for frank cards at regular rates, than to sponge upon the reading-columns for the transparent kind of news one sometimes finds there; yet we are sure that even that member of the *Telegraph's* editorial staff who is most severe upon the "old fogy doctors" that despise advertisers and will not consult with quacks, and do not believe that quinine gets into the bones, or that it is honest to pretend one thing and to practise another, would alter his opinion and the tone of his comments if he would but read the sketches of medical men in the *Daily Report* of San Francisco.

The point is simply this: A tradesman advertises his wares, but a professional man has only himself to advertise. The impropriety of such self-advertisement is obvious. We very much doubt that the editor of the *Telegraph*, or any other sane journalist, would be willing to intrust his own life, or that of any of his dear ones, to an advertising doctor.

The quack is strong, but his rule must sooner or later come to an end. A little more courage on the part of the medical press will end it sooner. Meanwhile, thanks and much power to the brave "S." of the *Pacific Medical Journal.*

AN EXHIBIT OF ROAD-MAKING AT THE COLUMBIAN EXPOSITION.

COLONEL ALBERT A. POPE, of Boston, is earnestly endeavoring to secure "a comprehensive exhibit of roads, their construction and maintenance, at the World's Columbian Exposition."

It has been alleged that bicycle manufacturers have a keen business interest in the matter, and it is doubtless true that good roads will help the bicycle business. So will they help every other business.

No class of men can have a greater interest in this question than physicians. To the discomforts and trials of a life not too full of sweetness, the wretched condition of city streets and country roads adds its full quota. Americans do many things well, and a few things badly; and among the things that they do worst is road-making. If COLONEL POPE can succeed in his effort to have at the Columbian Exposition an educational exhibit that shall attract prominent attention, and shall show what has been done elsewhere and what can be done in this country to secure good roads, he will have performed a substantial public service. The greatest difficulty to be contended with is, of course, the objectionable introduction of partisan politics into the management of public works throughout the country.

The recent exhibit by SECRETARY TRACY of the improvement attained in the navy yards since the principles of Civil Service Reform were introduced into their management is an illustration of what can be done in road-making when that shall likewise have been delivered from the control of the practical politicians and "the boys."

Of course, good roads cannot be made under any system until the principles of road-making are generally understood, and the proposed exhibit at the Chicagoan World's Fair will be an important factor in the diffusion of the knowledge of these principles. As good citizens, for the benefit of the public, and as physicians, for their own benefit and that of their patients, we would urge our readers to further the movement by every means in their power. COLONEL POPE suggests that letters to local newspapers and to members of Congress will be of material assistance.

REVIEWS.

CARDIAC OUTLINES FOR CLINICAL CLERKS AND PRACTITIONERS, AND FIRST PRINCIPLES IN THE PHYSICAL EXAMINATION OF THE HEART FOR THE BEGINNER. By WILLIAM EWART, M.D. Cantab., F.R.C.P., Physician to St. George's Hospital, etc. With sixty-two illustrations. 8vo, pp. x, 165. New York and London: G. P. Putnam's Sons, 1892.

THE study of physical diagnosis may be made to appear extremely difficult, or it may be reduced to the ulmost simplicity. Of course, a thorough knowledge of visceral anatomy is fundamentally necessary. In addition, the result will be governed by the method in which the subject is approached. The book before us affords adequate evidence of the correctness of the position here taken, and of the aid that well-written books may render in the study of practical subjects. Not only is that much of the subject with which the book has to deal presented in a clear and concise manner, but it is presented with so much interest that one is loath to put the volume aside, and one wonders why more books of the same kind are not brought forth, or rather wishes that they were. Not a little of the merit of the work belongs to the excellent and accurate illustrations. We can commend it most heartily to all that appreciate the value of careful clinical examination, and who desire to be fully and accurately and intelligently informed on a subject of incalculable aid and an indispensable adjunct in diagnosis. The merest summary of the contents of this excellent little work would carry us beyond the limits of this review. We cannot do better than refer

those interested to the original. It should go far toward stimulating the systematic practice of making careful clinical records.

A Treatise on Bright's Disease of the Kidneys: Its Pathology, Diagnosis, and Treatment. With Chapters on the Anatomy of the Kidneys, Albuminuria, and the Urinary Secretions. By Henry B. Millard, M.A., M.D., Fellow of the Academy of Medicine of New York, etc. With numerous original illustrations. Third edition, revised, enlarged. 8vo, pp. xviii, 322. New York: William Wood & Co., 1892.

The author states that since the appearance of the second edition he has devoted much time to retracing former experience and adding new; and that as a result of prolonged new investigation and observation he has changed many of his former opinions and conclusions, especially with reference to the existence of what is known "as physiological albuminuria." He states in Chapter VIII, which is devoted to this subject, that the experience of Capitan and Chateaubourg, upon which he formerly relied, must now be thrown out of consideration, on account of the defects in their methods of testing, which do not exclude the possibility of mistaking mucin for albumin.

Permanent albuminuria, even if intermittent, according to Millard's latest experience, usually implies, in some way, impaired health or some latent pathologic condition.

The book maintains its reputation as a careful, systematic study of its subject, and, while we do not necessarily agree with all of the author's opinions, we must admire the clearness with which he expresses his views, and commend the generally practical character of his advice as to treatment.

Uses of Water in Modern Medicine. By Simon Baruch, M.D., Attending Physician to the Manhattan General Hospital and New York Juvenile Asylum, etc. Two volumes. Pp. xv, 115; pp. viii, 228. Detroit: George S. Davis, 1892.

In a short compass, the author, who is an acknowledged authority upon the subject, gives the rationale and the principal methods of hydro-therapeutics. While we cannot fully indorse the somewhat enthusiastic statements made, we do believe that this important subject and these important means of cure have been greatly neglected by English-speaking physicians, and Dr. Baruch deserves grateful recognition for his efforts to secure a more extended knowledge and more appreciative use of the powers of water in medical practice.

If he had done nothing else than call attention to the merits of the Brand treatment of typhoid fever he would have rendered a valuable service to the community and to the profession. We trust that each of our readers will buy and study this little work.

Le Rachitisme. Par J. Comby, Médecin des Hôpitaux de Paris. (Bibliothèque Médicale. Charcot-Debove.) Paris: Rueff et Cie, 1892.

This is a most interesting as well as an attractively bound little volume of 175 pages.

Dr. Comby draws his deductions from a large practice among children. He clearly describes the malnutrition and general dyscrasia of rickets, and the digestive troubles that antedate deformities.

He draws the lines clearly as to congenital rickets, tardy rickets, osteomalacia, and osteoporosis. Very properly, he calls especial attention to the development of the disease during the age of dentition. Ignorance and poverty are the causes, not climate. The descriptions of the resultant bony deformities are good, but he fails to recognize the value of the prevention of these distortions, and he is not enthusiastic upon subsequent correction by surgical and mechanical measures. Osteoclasis is his favorite surgical procedure. Hygienically, good food, good air, salt baths, and cleanliness are the essentials. Calcicum phosphate, cod-liver oil, and phosphorus are valuable adjuncts to hygienic measures.

CORRESPONDENCE.

A UNIQUE MODE OF ADVERTISING.

To the Editor of The Medical News,

Sir: The subject of this communication is suggested by a memorandum in The Medical News, entitled "Copies of Advertisements Desired." For some time I have observed a scheme that is becoming more and more prominent, while its participants are multiplying in number and increasing in zeal. I refer to the indorsing of pharmaceutical preparations known as tablet-triturates, compressed tablets, or compressed pills, by prominent members of the profession.

A number of travelling salesmen call on me in the interest of their respective firms; they display their goods in an attractive array, and laud, in mercantile eloquence, the virtue, beauty, solubility, uniformity, and excellence of their wares, manufactured from the purest drugs, under the supervision of the highest commercial integrity. Preparation after preparation is presented; on examination I read on the label the name of a prominent professor of some university or medical school.

The agent insists on my purchasing the preparation because Professor —— uses it in the hospital. After declining to order the article, another bottle is produced, bearing the name of Doctor ——, who is the Chief Physician in some State Institution or Hospital.

In this characteristic manner a sale may be effected by an argument based not on the merits of the preparation, but on the name of the doctor that indorses the label, as a stamp of approval.

I am in a position to know that many of these preparations are bought and prescribed, not because of their intrinsic value, but by reason of their high indorsement, and that they are used under the name of the indorser.

Recently, during a consultation, the attending physician informed me that the patient was taking Professor ——'s triturates. Not being acquainted with the preparation under that name, I inquired what they contained, and to my astonishment the physician did not know all of the ingredients, but assured me that it was the proper thing to give, because Professor —— recommended it. Many are thus influenced to use drugs not suited to the case, and with the therapeutical value of which they are unacquainted.

It is not my object to argue in favor of or against these preparations. I only claim that, to use drugs under such a title is unscientific, while this mode of advertising is a departure from ethical consistency, if not a direct violation of the code.

Furthermore, that its influence is deleterious no one can question, and that great responsibility lies with those who engage in it.

We do not blame the trade for resorting to a measure that is so profitable, but we are forced to censure those who suffer their names to appear in every pharmaceutical catalogue, to be used as commercial instruments by anyone who chooses to appropriate them.

These compounds should not be sold over the signatures of men that occupy high places, men that we are to regard as masters in the profession, and those whose names grace the pages of medical literature.

I regret to state that I have in my possession a list of over seventy names of this superior type, all of which appear in pharmaceutical catalogues.

If these gentlemen are not aware of the fact that their names and reputations are thus misused they should be informed of the truth; and, on the other hand, if they are cognizant of the fact, and tolerate it, they are fostering an evil the influence of which is far-reaching and more potent than they imagine.

In the *Times and Register*, vol. xxiii, p. 245, I am pleased to note that Professor Da Costa repudiates the authorship of one of these preparations. It is known as "Da Costa's Heart Tonic." Professor Da Costa takes the proper position in this matter, and indicates a mode by which this evil can be combated.

H. F. SLIFER, M.D.

NORTH WALES, PA.

THE METAMORPHOSIS OF MICROÖRGANISMS.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS (May 7, 1892) William C. Braislin, of Brooklyn, N. Y., makes the statement that over fifteen years ago Professor Tyndall said, in regard to the propagation of bacteria: "No change of any isolated organism into another organism is ever observed."

Is this now an accepted fact by bacteriologists, or is there not yet some doubt about it? Has it not been proved by Naegeli that the bacterium that causes lactic-acid fermentation in milk may be changed by cultivating it in extract of meat and sugar, so that it will no longer produce a lactic but an ammoniacal decomposition in milk. And is it not the conclusion of H. C. Wood and Formad that the micrococci found in diphtheria resemble those found on furred tongues in all respects, except in their greater tendency to grow, and when cultivated successfully they lose their contagious powers and grow less rapidly. Do not these authors, therefore, consider that the common micrococcus by cultivation can be converted into a rapidly growing diphtheritic micrococcus, and by change of cultivation reverts to the common type? Most truly,

W. H. BARR.

AGRICULTURAL COLLEGE, MISS.

The foregoing letter was submitted to Dr. Abbott, who kindly replies as follows:

The statement of Tyndall related more to the constancy of morphology than to the general biologic peculiarities of bacteria, and subsequent observations have demonstrated its accuracy. There is no evidence in support of the opinion that a bacterium belonging to the family of rod-shaped organisms, the bacilli, can ever alter its shape and become constantly spherical or spiral; *i.e.*, a micrococcus or a spirillum, and *vice versâ*. The morphology of members of these different groups is constant. With the physiologic activities of the bacteria, however, the conditions are different, for an organism that, under a given set of circumstances, is concerned in the manufacture of one chemical product may, with altered surroundings, such, for example, as a different kind of nutrition, presence or absence of oxygen, alkaline or acid reaction of the medium in which it is growing, etc., generate substances of an entirely different nature chemically. In the light of more recent studies upon diphtheria there is no reason for considering either in whole or detail the work of Wood and Formad, and it is not probable that the authors themselves would to-day insist upon the acceptation of the statement made by them upon this subject so long ago. The work of Wood and Formad has never received confirmation since the time of its publication.

A. C. ABBOTT, M.D.,
First Assistant, Laboratory of Hygiene, University of Pennsylvania, Phila.

THE ADDITION OF A FIFTH RULE TO THE FOUR OF KOCH.

To the Editor of THE MEDICAL NEWS,

DEAR SIR: In the very valuable contribution which Dr. Sidney Martin, in the Gulstonian Lectures, has made to chemical pathology, of which you have given a very complete editorial review in your issue of July 9th, the learned author states that to the four rules of Koch there should now be added a fifth, namely, that "The chemical poisons must be obtained from the tissues in the natural disease, and products with a similar physiological action proved to be formed by the primary infective agents when grown outside the body."

In this connection I think that I am justified in calling attention to the following quotation (*Journal of the American Medical Association*, vol. xiii, p. 831), taken from a paper read by myself at the Newport meeting of the American Medical Association in June, 1889: "I think that it is now time for us to supplement the rules of Koch with the following, which should be insisted upon in those cases in which the lower animals are not susceptible to the action of the germ. Before any microorganism can be considered the true and sufficient cause of a given disease, it must be shown that the chemical products of that germ are capable of producing the characteristic symptoms and lesions of that disease in an acute form."

The same statement is reported in the second edition of *Ptomaïnes and Leucomaïnes* (Vaughan and Novy), 1891, pages 97–98.

In the discussion which followed the reading of my paper at Newport one of the most renowned of American bacteriologists (see page 836, vol. xii, *Journal of the American Medical Association*) protested against my proposed rule.

Now, three years later, Dr. Martin formulates the same rule. If the principle of this rule is right, America deserves the credit of first having formulated it.

Respectfully, VICTOR C. VAUGHAN.

MICHIGAN UNIVERSITY.

A SIMPLE ENDOSCOPE.

To the Editor of THE MEDICAL NEWS,

SIR: Some time since I was consulted by a young man afflicted with considerable urethral irritation, the result of a previous gonorrhea. There was no discharge, only considerable pain at the commencement of the urination, referred to the head of the penis. He had applied to various physicians and had tried various remedies without avail; the last physician had been passing bougies. As he had pretty well made the rounds of treatment, I decided to try galvanism. Accordingly, I made two applications a week by means of a urethral electrode of a sensible current, and in the course of three weeks had the irritation very much lessened; but by none of the many methods subsequently pursued could I entirely remove the pain. Finally, I succeeded by the employment of a little apparatus, which I shall endeavor to describe, and which I trust may be of service to others who may be similarly situated. Confident that there were spots of inflamed mucous membrane along the urethral tract which I had heretofore been unable to reach satisfactorily, and which had kept up this long-standing irritation, I felt the need of an endoscope with which to find them. This, however, was an instrument which I did not possess, and indeed an instrument which I fancy few do possess, except those who make a specialty of genito-urinary diseases.

Accordingly, I constructed an instrument that answered my purpose admirably. I made it of an ordinary glass "straw," such as is used for imbibing lemonade and kindred beverages, though any like medium-sized glass tube, with a round smooth extremity, would do as well. Heating this about four inches from one extremity in the flame of an alcohol-lamp, I broke off the longer portion and at the same time sealed the smaller. Holding the same part again in the flame, and at the same time gently blowing through the other end, I gradually expanded the fusing extremity into a sort of bulb. The top of this bulb I broke off, smoothing the jagged edges by slightly melting them in the flame. I now had a sort of glass funnel expanded at one extremity, and of the same caliber for three inches of its length. When next my patient came, applying a little glycerin on the outside of this homely "endoscope," I found it could easily be slipped its full length into the urethra; and by means of an ordinary head-mirror I could throw a light down to the termination of the instrument, and plainly see the condition of the mucous membrane at any point by simply slipping the glass-tube up and down. Discovering, as I expected, a number of patches of inflamed mucous membrane, I was enabled by this means to make application of various stimulating and astringent substances to these particular spots, applying even as strong as a 40 per cent. solution of silver nitrate, and in a few weeks had his long-standing irritation entirely removed.

Respectfully,

ERNEST B. SANGREE.

744 SOUTH FIFTEENTH ST.

CYSTOSCOPY.

To the Editor of THE MEDICAL NEWS,

SIR: In vain have I looked through the literature to learn if anyone has succeeded in viewing the whole interior of the bladder at once. The end can be accomplished by an exceedingly simple method: All that is necessary is to put the woman in such a position that the contents of the abdomen gravitate toward the diaphragm and insert Simon's well-known urethral speculum. It is possible that occasionally failure will occur. If the intra-abdominal pressure is great, as in very fat women, etc., I place the hips on the upper edge of a lounge in dorsal decubitus. I shall not dwell upon the advantages and increased possibilities of surgical action resulting from the use of the endoscope, but I expect that as good results will some day be obtained in males as are now secured in females. It seems to me that after a straight tube is introduced into the bladder with the patient in the position indicated, and a strong light thrown in, a small mirror (fastened to a wire at an angle) could be introduced, and thus the whole bladder be surveyed by turning the mirror in various directions. The shorter the tube and the greater the caliber, the better the view that ought to be had. The common urethral endoscopes are too long for this purpose, as the penis can be crowded together a great deal. Not possessing the opportunities of the post-mortem room, I would suggest that those who have such opportunities might apply the idea here expressed. The present armamentarium (Nitze, etc.) is needlessly complicated, and brings into view at one time smaller areas than would be seen in the device that I propose. If this model of a laryngeal mirror were convex, still larger areas could be seen at one time, but, of course, in reduced size. All endoscopes at present in use require the bladder to be filled with water. The method here outlined, dispensing, as it does, with the use of all fluids, would certainly command a better view of the interior of the bladder.

Respectfully, MARCELL HARTWIG.

BROOKLYN, N. Y.

NEWS ITEMS.

The American Orthopedic Association will hold its sixth annual meeting at the New York Academy of Medicine, September 20, 21, and 22, 1892. The following program has been arranged:

First Day—September 20th.

The President's Address, by Dr. Benjamin Lee, Phila.

"Report of a Case of Spontaneous Dislocation of the Hip-joint," by Dr. B. E. McKenzie, Toronto.

"Adduction following Fracture of the Neck of the Thigh bone," by Dr. H. Hodgen, St. Louis.

"Osteitis Deformans; with a Report of Two Cases," by Dr. Henry Ling Taylor, New York.

"Lateral Dislocation at the Knee-joint Due to Local Disease, or Paralysis, with Especial Reference to Treatment," by Dr. T. Halsted Myers, New York.

DIPHTHERITIC CONJUNCTIVITIS: REPORT OF TWO CASES, WITH THE BACTERIOLOGIC STUDY OF THE FALSE MEMBRANE.[1]

BY HIRAM WOODS, M.D.,
OF BALTIMORE, MD.

UNDER the terms membranous, croupous, and diphtheritic conjunctivitis there has been described a variety of affections of the conjunctiva, the essential feature being the formation of a pseudo-membrane. The disease may be trivial, getting well under little or no treatment; or it may be the most dangerous of all of the conjunctival diseases, and destroy the eye, despite all one can do.

An attempt has been made to divide the pseudo-membranous inflammations of the conjunctiva into two classes, according to the situation of the false membrane. Thus, a plastic deposit sometimes forms on the palpebral conjunctiva during the course of a catarrhal or purulent conjunctivitis. Again, with only the symptoms of simple conjunctivitis, and without any purulency, a similar membrane may form. It is usually attached feebly to the conjunctiva and can be wiped off. Again, it may be more firmly adherent. When it is removed, the subjacent conjunctiva is found succulent and vascular, with, possibly, little bleeding spots marking the points of attachment of the false membrane. The ocular conjunctiva is not involved, and the lids are not indurated. To this form of the affection the name "croupous" or "membranous" has been applied by some authors, including Alfred von Graefe, Saemisch, Schmidt-Rimpler, Swanzy, and Macnamara. "The pathological process," says Bull in Soelberg-Wells's *Treatise*, "here consists mainly in the deposit of an albuminous exudation, probably fibrin, upon the surface of the inflamed conjunctiva, which deposit rapidly coagulates on exposure to the air, and thus assumes the form of a membrane. This deposit contains cells which have made their exit from the mucous membrane, and upon the number of these cells depend more or less the firmness and density of this membrane. . . . . Micrococci have sometimes been found in the secretion of croupous conjunctivitis, but not always."

A second variety of pseudo-membranous conjunctivitis is seen, to which the term "diphtheritic" has been applied. Here, early in the disease, the eyelids become swollen, hard, and, to all appearances, bloodless. It is always difficult and often impossible to evert them. There is either no discharge at all from the mucous surface, or it is watery. The palpebral and ocular conjuntiva is covered with a thick gray membrane. If an attempt be made to strip it off, it is found firmly adherent. If incised, the conjunctiva and lid-tissues are found infiltrated with this dense plastic material. The incision will be bloodless. This condition persists for several days, when purulent secretion sets in as the second stage. The lids become softer and the swelling disappears. The third and last stage is that of cicatricial contraction in the conjunctiva and lid-tissues. It will be seen that in the course of diphtheritic conjunctivitis, as described, the cornea is subjected, during the first stage, to the dangers of plastic infiltration and strangulation from the pressure on the vessels of the ocular conjunctiva; during the second, to the dangers of purulent ophthalmia; and, if it survive all this, it may eventually be made opaque by the cicatrization of the lids.

To summarize: the classical distinction between croupous or membranous, and diphtheritic conjunctivitis is this: In the former a false membrane forms *on* the conjunctiva, is limited to the palpebral portion, and when stripped off leaves the mucous membrane vascular. Diphtheritic inflammation invades both the palpebral and ocular mucous membrane, cannot be stripped off, infiltrates the tissue of the lids, and renders them hard, swollen, and bloodless. If the term diphtheritic were here used etymologically, and conveyed the idea only of a membranous formation, this distinction, though an arbitrary one, would suffice for clinical purposes. But there is inseparably associated with the word "diphtheritic" the idea of diphtheria; and "diphtheritic conjunctivitis" gives the impression of being a manifestation upon the ocular mucous membrane of this disease. Here one meets two facts that render a distinction, based upon the presence or absence of lid-infiltration, untenable, at least in the opinion of many, among them such authors as Nettleship, Jüler, Bull, and Noyes. These facts are (1) the production of a pseudo-membranous conjunctivitis, with hard lid-infiltration, by agents *not diphtheritic;* and (2) the large amount of clinical evidence that pseudo-membranous conjunctivitis occurs as a complication or

[1] Read before the Medical and Chirurgical Faculty of Maryland, April 29, 1892.

starting-point of diphtheria, the lid-infiltration being often absent. Soelberg-Wells, Nettleship, and others record the occurrence of lid-infiltration—clinically, diphtheritic conjunctivitis—from inoculations with gonorrheal pus, the too free use of caustics, and traumatism. Noyes mentions a case of his own "in a boy, ten years of age, operated upon for strabismus; the dense, gray, plastic infiltration extended from the wound over the ocular and then over the palpebral surfaces, with the typical characteristics of stiff and bloodless structures." One of the cases I shall presently report presented just such appearance, but there was no possibility of a diphtheritic origin.

Among the proofs that pseudo-membranous conjunctivitis occurs as a manifestation of diphtheria are the following: it has been found to prevail epidemically with diphtheria; to often precede faucial diphtheria, or to occur during its course; to be, apparently, a source of contagion for diphtheria to other persons, or to be contracted from another having diphtheria. Many of the cases of diphtheritic conjunctivitis occur either in connection with pseudo-membranous angina or alone, after the infectious diseases, scarlet fever and measles—so-called secondary diphtheria. Bacteriologic investigations have, I know, recently shown that many of these secondary diphtherias are not of the same nature as primary diphtheria, and should not be so termed. Still, until the demonstration of the Loeffler bacillus as the cause of primary diphtheria, they were so called, and are, I believe, clinically indistinguishable from the primary disease.

Concerning the occurrence of diphtheria of the conjunctiva, without lid-infiltration, Noyes records two fatal cases of diphtheria, which were first reported by Nettleship, in both of which the first manifestation of the disease was upon the conjunctiva, from which it spread to the nose and throat. There was never the lid-infiltration thought to be the diagnostic feature of diphtheritic conjunctivitis. It seems, then, impossible to separate croupous and diphtheritic conjunctivitis by objective appearances. Noyes proposes the term "plastic conjunctivitis" for all pseudo-membranous ophthalmias, irrespective of lid-infiltration, save those in which constitutional sysmptoms appear. These should be called "diphtheritic." It would seem more exact to limit the term to those cases occurring either alone, or in connection with pseudo-membranous angina, in which the Loeffler bacillus is found. It is doubtful, however, if this is practicable. So far as we know at present, the presence or absence of the bacillus diphtheriæ in plastic infiltration of the lids would affect treatment not at all, and prognosis very little. Add to this the difficulties of a bacteriologic examination, and it is probable that the adoption of Dr. Noyes's suggestion is the nearest approach to exactness that can be expected.

There is very little to say about treatment. The most important thing is not to use astringents during the first stage—that of plastic infiltration. They can only do harm. This is about the only point in the treatment of the first stage upon which there is a consensus of opinion. One finds the same thing here that is found in other intractable diseases—the suggestion of a host of remedies. Cold and antisepsis seem to meet with favor most generally. I fear, however, that the following from Soelberg-Wells comes near the truth: "We have, unfortunately, but little control over the disease during the first period." During the second stage—that of purulent secretion—the principles that govern the treatment of purulent conjunctivitis will hold.

I have seen four cases of diphtheritic conjunctivitis. It is a very rare disease. Two occurred in the private practice of Professor Chisolm, who kindly allowed me to examine them.

One was in a girl, sixteen or seventeen years old. Only one eye was affected. There was board-like infiltration of the lids and conjunctiva. The eye was lost. There was diphtheria in the house at the time, but the conjunctivitis was the only evidence of diphtheria in this girl.

Professor Chisolm's other case was seen at the Presbyterian Eye and Ear Hospital two years ago. An old gentleman had undergone cataract-extraction. For a week his case progressed smoothly. Then a slight catarrhal conjunctivitis set in. A weak solution of silver nitrate was used once a day, and the eye was kept clean. Suddenly the lids became enormously swollen in the course of two or three days. A membrane appeared on the palpebral and ocular conjunctiva, infiltrating the lid-tissues, and the cornea sloughed. There had been no exposure to diphtheria. Professor Chisolm tells me that he sent a piece of the pseudo-membrane to Professor Welch, who pronounced it non-diphtheritic.

Both of my cases occurred in the practice of Dr. S. W. Seldner, who kindly referred them to me.

Case I.—On the afternoon of December 20, 1889, Dr. Seldner asked me to see Joe H., six years old. The Doctor himself had been called in only on the same day. From the parents I learned that the child had just recovered from measles. It had not been thought necessary to send for a physician. They had not even kept the boy in bed. For two or three days the child had been complaining of his eyes. Within thirty-six hours, certainly, of the time Dr. Seldner, the family physician, had been sent for, the pain had greatly increased, and the lids had become so swollen as to close the eyes. There had been a little watering. The child was crying from pain when I entered the room. The lids were swollen, hard, and tense. The integument had a waxy appearance, and seemed bloodless, save for

two or three engorged veins. The lightest touch caused intense pain. It was necessary to administer chloroform before the eyes could be examined. This done, the lids were forcibly separated, and partly everted. Complete eversion was impossible. There was no discharge. The conjunctiva of each eye was covered with a thick gray membrane, extending from the lid margins, above and below, over the palpebral membrane, the fornix, and ocular conjunctiva to the cornea, where it abruptly terminated in a hard, slightly elevated ring. A few small ecchymoses were visible on that part of the false membrane covering the lids. By rather vigorous rubbing with a piece of absorbent cotton a few threads of the membrane were detached from the lid. The subjacent surface was dry, hard, and of the same color as the rest of the false membrane. There was a haziness about each cornea, but no point of ulceration. The pupils were moderately contracted—probably from the chloroform. The anterior chambers were of normal depth. After the child had recovered from the anesthetic, I carefully examined his throat and nose, but found no evidence of diphtheria. Ice-compresses, to be kept on constantly, and the hourly washing with a 1:5000 solution of mercuric chloride, were ordered. At the same time, the hazy look of the cornea induced me to put a drop of atropine into each eye. Leeches were considered, but were rejected on account of the boy's feeble condition.

The temperature was elevated, and remained so for several days, the variations being from 100° to 102°. It was generally a fraction over 101°, and varying very little. A mixture of quinine and iron, ordered by Dr. Seldner, was continued. I saw the boy again at 8 P.M. He was easier, and wanted the cold applications all the time. The objective appearances were unchanged, save that each pupil was somewhat dilated by the atropine, the left more so than the right. I now made an incision into the hard, elevated ring around the right cornea, through the conjunctiva, to the sclerotic. There was not a drop of hemorrhage. Cold and the corrosive wash were continued during the night, as well as two instillations of atropine. The next morning (December 21st) the appearance of both lids and globes was practically unchanged. The pupils had not been affected by the atropine, probably on account of poor absorption. There was pain on touching the lids, but otherwise not much suffering. That evening the boy was again in pain, the cold failing to relieve him. Both corneæ were more hazy, but I was not able to find a point of ulceration. Hot applications were now substituted for the ice. I was led to make this change because the cold was no longer relieving the pain, and I thought the corneæ might stand a better chance with hot than with cold applications. Again, I was influenced by a statement of Nettleship's, that when cold fails to benefit, heat may increase the fluid exudation, and determine blood to the lids. Thus, the approach of the blennorrheic stage might be hastened.

The next morning (December 22d) the appearance was unchanged. The corneæ, though hazy, were both transparent. While I was inspecting the right eye, the boy made a sudden movement of the eye upward, possibly increasing the pressure on the weakened cornea. The aqueous gushed out through a pinpoint perforation that was invisible. That evening, as I very gently raised, as well as I could, the hard lid, I found on the left cornea what I at first thought to be a thread of membrane. It proved to be a corneal slough, and when the pressure of the lid was removed, lens and vitreous gushed from the globe.

The next morning (December 23d) I found that the right cornea had sloughed during the night. The blennorrheic stage did not set in for eight days after the eyes were lost. A piece of the false membrane from the right upper lid was taken to Dr. Alexander C. Abbott, then of the Johns Hopkins Hospital. I am unable to say by what methods Dr. Abbott examined the membrane, but his well-known skill leaves no doubt of their thoroughness. He found an abundance of organisms—the streptococci being present in large numbers—but nothing that would justify him in calling the case one of primary conjunctival diphtheria. The Loeffler bacillus was not present.

The family to which this boy belonged consisted of five children, a daughter of seventeen, my patient of six, and three little boys, one and a half, two and a half, and about four years old, respectively. There had been nine children in the family, and three of them had died, some years previously, within a few days of one another, from diphtheria, secondary to scarlet fever. When I was called to see Joe, on December 20th, I found his brother Frank, the baby, suffering from acute otitis media, which had come on, according to the parents, during an attack of measles early in December. On the 24th, Dr. Seldner told me that the two other boys had been taken ill. Both had a slight eruption which we thought scarlatinal. On the 25th, the diagnosis was unmistakable in the four-year-old boy, Albert, while the eruption was indefinite and pale in the child two and a half years old. There was, however, a diphtheritic membrane in this boy's nose. Several times this little fellow nearly strangled, and finally died of exhaustion on January 6, 1890. Albert's case was complicated by a purpuric eruption on the legs, and the formation of blood-crusts about the lips. He seemed, however, in a fair way to get well. On the 5th of January, Frank, the baby, who was said to have had measles early in December, was taken with faucial diphtheria, which rapidly spread to the larynx, and he died on the next day, a few hours after his brother. On the same day (6th) Albert, who, we thought, was convalescent, was taken as Frank had been on the 5th, and died on the 8th. I have always regretted that I did not try to get a bacteriologic examination of the false membranes in these three cases. Neither Dr. Seldner nor I had, however, any doubt of the diagnosis, and I personally did not then appreciate the importance of such examination as I do now.

Case II.—On March 16th last, Dr. Seldner sent for me to see E. S., a boy, three years old. The child had recovered from measles several days previously, when on March 12th a membrane appeared

in the pharynx. On the following day, membrane was also found in the nose. The father of the child noticed some swelling of the right upper lid on the 15th. On the morning of the 16th he discovered that the left eye was watering and closed. On the afternoon of this day I saw the boy. I found in the pharynx a pseudo-membrane. The nostrils were obstructed, but whether with false membrane or secretion I did not determine. The lids of both eyes were somewhat, but not greatly, swollen. The right lid was easily everted. A gush of tears led me to carefully inspect the cornea, and a small ulcer was found. The conjunctiva was dry, and entirely free from false membrane. The lids of the left eye were harder, and it was more difficult, but not impossible, to evert them. The upper lid was lined with false membrane, from the margin to the fornix. The conjunctiva of the lower lid and globe was not invaded by the membrane. A piece of the false membrane was stripped off, and the conjunctiva found gray and infiltrated. The cornea was clear. Cold and a 1:3000 corrosive solution were ordered. Atropine was also used. Dr. Seldner was treating the boy constitutionally. On the 17th, about twenty-four hours after my first visit, I found both pupils moderately dilated from the atropine, but the swelling and hardness of the lids were unchanged. The pseudo-membrane had extended from the conjunctiva of the left upper lid to that of the globe and lower lid. It had also appeared on the right upper lid. At 2 A.M. on the 18th the boy died of suffocation. The piece of membrane removed on the 16th was taken on the same afternoon to Dr. Simon Flexner, Professor Welch's assistant. I also took Dr. Flexner to see the child on the 17th, and he obtained cultures from the throat and left eye. His report is appended:

"The first cultures were made from the membrane which was brought me in water. The first tube from this consisted almost, if not entirely, of the short bacilli, which I regarded then, and am still inclined to the same idea, as having been extraneous. The succeeding tubes from the membrane showed fewer bacilli, and more organisms, consisting chiefly of chain-cocci. This would seem to indicate that the bacilli were on the surface of the membrane only, and could readily have been derived from the water. As the deeper parts of the membrane were reached, these organisms were not present, at least not in predominating numbers, as they were in the first tube.

"The second examination comprised both the eyes and the throat. In neither of these cases were the bacilli before-mentioned observed, and these cultures were taken directly from the patient. In these the predominating organisms consisted of chain-cocci (streptococci). This was true of the throat and the eyes, and the cover-slips, made directly from the exudation, showed this, as well as the cultures. It is true a bacillus was found, but in small number, and it was excluded from being the diphtheritic bacillus of Loeffler. Its morphology was different, and its culture-properties also.

"I do not see any escape from viewing this process as of streptococcus origin. There were no organisms present which rendered the diagnosis of diphtheria probable; and, on the other hand, we know that there are pseudo-membranes produced in the throat, nose, and eyes in which the streptococcus is the exciting cause. . . . It is very probable that the pseudo-membranous affections of the air-passages and conjunctiva in scarlet fevers are due to a streptococcus."

Were it not for the deaths of the three little brothers of my first patient from what seemed a virulent form of diphtheria, there would be no reason to doubt that the diphtheritic conjunctivitis was of the same origin and nature as in my second case. There are several standpoints from which these cases may be viewed, among them: First. That all were secondary to scarlet fever or measles, and non-diphtheritic. In favor of this one notes (*a*) that pseudo-membranous affections, after infectious diseases, are now known to be usually non-diphtheritic; (*b*) that Dr. Abbott did not find the Loeffler bacillus in the ocular pseudo-membrane; (*c*) that, although Dr. Seldner did not see either of the so-called cases of measles occurring in my patient and the baby, Frank, early in December, it is quite certain that both of these children had either measles or a very light form of scarlet fever; also that one of the two children taken ill on December 24th certainly had scarlet fever, and there is very little doubt in the case of the other. Against the view of secondary origin must be noted the virulence of the throat-affection, the interval of nearly a month between the disappearance of the measles in the case of the baby and the appearance of pseudo-membranous throat-trouble, and the occurrence during this month of my case and two fatal cases of what was clinically malignant diphtheria. A second possibility is that my case was non-diphtheritic, and that the child in whose nose we found a membrane on December 25th—twenty-four hours after he was taken ill—had contracted primary diphtheria from an independent source, and infected his brothers. Thirdly, it is possible that all four cases were diphtheritic, the bacillus in the ocular pseudo-membrane remaining, for some reason, undiscovered.

In the literature of diphtheria there are only incidental allusions to the bacteriology of pseudo-membranous conjunctivitis. The few that I have found I owe to the kind help of Professor Welch. Artificial conjunctival diphtheria has been produced in cats by inoculation with the Loeffler bacillus. The bacillus has also been found in pseudo-membranous conjunctivitis occurring in connection with diphtheria.[1]

In a case reported by Trousseau,[2] secondary to measles, with loss of both eyes, and occurring in

[1] Kolisko and Paltauf: Wiener klin. Wochenschrift, 1889, No. 8.
[2] L'Union Médicale, 1887, No. 9.

connection with multiple abscesses and bronchopneumonia, Darier found the conjunctival pseudomembrane swarming with organisms, but he did not find the Loeffler bacillus.

The following propositions concerning pseudomembranous conjunctivitis seem to me justifiable:

1. There are two varieties: one of the same nature as primary diphtheria; the other apparently a sequel of many and widely different pathologic conditions, having no relation to diphtheria. "Plastic conjunctivitis" seems the most appropriate term for the latter variety.

2. The classical distinction between diphtheritic and membranous conjunctivitis, based upon the presence or absence of infiltration in the tissues of the lids and ocular conjunctiva, is inadequate.

3. The only absolute proof of the diphtheritic nature of a pseudo-membranous conjunctivitis is the demonstration of the Loeffler bacillus, or later, the occurrence of paralysis, or some other sequel of diphtheria. Clinically, the presence of constitutional symptoms is essential to such a diagnosis.

4. The cause of the pseudo-membrane in plastic conjunctivitis is not certainly known, and probably it is not always the same. In some cases, at least, there seems good reason to attribute it to the invasion of streptococci, an infectious disease, or catarrhal conjunctivitis, or traumatism, or scrofulous habit, or some other influence lowering the resistance of the tissues and paving the way for infection.

5. Plastic conjunctivitis may be more dangerous to the eye than a pseudo-membranous inflammation undoubtedly diphtheritic, experience showing that the danger is in direct ratio to the degree of lid and conjunctival infiltration.

515 NORTH HOWARD STREET.

INSANITY IN PRIVATE PRACTICE.[1]

BY RICHARD DEWEY, M.D.,
MEDICAL SUPERINTENDENT STATE INSANE HOSPITAL.
KANKAKEE, ILLINOIS.

To one who has had some experience in the care of the insane the first idea that presents itself when considering insanity with reference to its occurence in private practice is the great disadvantage of a medical education that fails to provide the average practitioner with any adequate knowledge of insanity.

The courses of instruction given at a majority of our medical colleges are such that it is possible for a man or woman to graduate in medicine and enter upon practice without ever having seen an example of insanity, or having gained any intelligent idea of the etiology, clinical history, diagnosis, prognosis, or treatment of insanity.

[1] Read before the Illinois State Medical Society, May 18, 1892.

These courses of instruction lay a foundation whereon a knowledge of most of the physical diseases may be built; but in reference to insanity, the fact that it has a physical basis in pathology is but imperfectly understood, and there is often even in the minds of otherwise able and intelligent physicians great ignorance, and even superstition, upon this subject. The older ideas of demoniacal possession or some mysterious and unexplained fatality have scarcely been outgrown. A disease that affects the operation of the mind is apparently removed from the category of ordinary diseases, and there is introduced a new and strange element that seems an insoluble puzzle.

The complete elucidation of the interdependence between the brain and the mind is not, in the present state of knowledge, possible. Griesinger, in his classical treatise, remarks that if some higher intelligence were to descend to us and endeavor to explain the manner in which insanity is produced our own intelligence would not be sufficient to grasp the explanation. This is probably true, and yet we are loath to admit that the subject is beyond comprehension. A famous professor of mathematics once remarked to me when I quoted Griesinger's statement to him, that if an explanation were offered him from any source he would try mighty hard at least to understand it. In the years that have elapsed since Griesinger wrote, it must be admitted that great progress has been made in arriving at a comprehension of the mode in which insanity is produced.

Years of experience with bodily diseases are of little assistance to the physician in coping with mental diseases, unless a solid foundation in nervous pathology has been laid. Metaphysical conceptions of mind render it difficult to understand that there is a physical basis for the disease, and in meeting a case of insanity the unaccustomed practitioner is suddenly confronted with a situation the key of which seems to have been lost. He is likely to think that it has been thrown into the deep well of metaphysical speculation, but in reality it is accessible, and it is only necessary to dig a deeper stratum of the same science of pathology that has been his guide in other diseases; but the opportunities for that deeper study have been lacking to most practitioners, and thus the "things that are not confound the things that are." The only remedy for this confusion is the thorough study of the anatomy, physiology, and pathology of the brain and nervous system as illumined by the newer researches of recent years.

The sciences of neurology and psycho-pathology are in their infancy, but great progress is being made at the present time in their elucidation. To the general mind there is an element of awe and mystery in insanity, and many a general practitioner

when brought face to face with an acutely insane patient may say, with Shakespeare, (substituting "insanity" for "conscience,") "thus insanity doth make cowards of us all," and he feels a degree of anxiety and confusion that are fatal to coolness of judgment. The masterly control of the situation which is his in ordinary cases is gone, and under such circumstances the disposition manifests itself to pass the case on, to call in the aid of extreme measures or to unload the responsibility in any manner that may be possible. In the larger cities it is often practicable to secure the advice of one who is familiar with the specialty, but the larger number of such cases occur in situations where they are beyond the reach of expert counsel, and the family physician is compelled to take charge of them, and do the best he can, and in dealing with them is in danger of making one or another of several common mistakes.

First. He may hurry the patient off to a hospital when such a course is not really necessary.

Second. He may keep the patient at home until some unfortunate casualty occurs, or until the most favorable time for treatment has forever passed away.

Third. In dealing with the case he may make unwise and unnecessary use of powerful nervines, sedatives, and narcotics. He may resort to harsh measures of restraint which are unnecessary, or he may indiscriminately indulge the whims and vagaries of the patients or their friends in such a manner as to be harmful.

In endeavoring to lay down a few lines for guidance in this matter I will briefly offer some suggestions under the foregoing heads.

The reason for the embarrassment of the general practitioner is that he has had little or no opportunity of studying normal or diseased brains, either clinically or pathologically; and a great advantage might be gained in this respect by almost any practitioner who would lay out a course of reading on this subject, and would utilize every opportunity that offered for examination and study of brains, both normal and diseased; and for the convenience of anyone not familiar with the literature I append hereto a list of works that would be of value in such a course of study:

Sanity and Insanity (Mercier). Manual of Lunacy (Winslow). Mickle, on General Paralysis. Clouston. Landois. Bucknill and Tuke. Nerve-Prostration (Roose). Familiar Forms of Nervous Diseases. Diseases of the Nervous System (Gowers). Spitzka. Maudsley. Physiology of Mind (Carpenter). Lehrbuch der Psychiatrie (Krafft-Ebing).

On taking up the possibilities of error in dealing with a case of insanity in private practice I will speak of

First. Sending the patient too soon, or unnecessarily, to an insane hospital.

The sending of a patient to an institution for the insane is a grave step, and the decision on this point is often a difficult one.

The consequences are serious, especially as the insanity thus becomes a matter of public notoriety and record, and there is no denying that this is an injury to an individual in business and social life. Although the more enlightened opinion of the day recognizes insanity wholly as a disease, there is in the minds of many still an association of something disgraceful in connection with it, and in our own State of Illinois this fact is emphasized by the operation of the law that compels all insane persons to appear in court and be tried by a jury (?) before they can be sent to an institution for the insane.

An anxious question of the patients and of their friends in such cases is as to the treatment the patient will receive if sent to an institution. There is, undeniably, in the public mind an attitude of suspicion toward institutions for the insane, and a greater readiness to believe ill than well of them. Without attempting to discuss this, it can only be said on this point that, while there is nothing perfect in this world, and abuse and neglect may occur in such institutions, the greatest pains are, I believe, universally taken by those in charge to avoid abuse and neglect, and with my knowledge of this matter I feel justified in saying that the chances of patients in respect of their treatment are better in than out of the hospital. The care of the patient's own family and friends is very likely to be injudicious, and not only injudicious but cruel. Some of the greatest barbarities I have ever known to be inflicted upon the insane were inflicted by their own family and friends, and it is my belief that there has been more illegal confinement and harsh and injudicious treatment in their own homes than in institutions.

The two things to be considered in deciding about sending a patient to the hospital are, whether there is serious risk to the patient himself or to others in keeping the patient at home; and whether the patient's own proper care and chance of cure require the supervision of the hospital.

To determine if there is serious risk it will be necessary among other things to consider whether there are hallucinations, auditory or visual, or of the other senses, which make the patient dangerous; whether there are tendencies toward suicide or homicide; whether there are perverted instincts or impulses to acts of violence, destruction, or outrage, and whether there is a prolonged loss of sleep or of food.

It is necessary to remember that in going to the hospital the patient comes in contact with others, and that such contact may be harmful, though every

effort may be made to avoid the harm from this source. In every well-regulated hospital special efforts are directed toward curative treatment and toward avoiding every association or contact that might be injurious.

The advantages at home are that the patient has the personal care of friends, and is not associated with other patients, and is in familiar surroundings. Certain forms of insanity may be more susceptible of care at home than others. Among these Hughes[1] mentions the insanity of pregnancy, childbirth, and lactation, alcoholic insanity, tuberculous or paralytic or senile insanity, to which I would add cases of hysteria, neurasthenia, and habit cases, generally of morphine, alcohol, etc., and also of helpless, feeble, and simply fatuous cases, although acute dementia may be marked by sudden violent outbreaks, necessitating the restraint of a hospital; and furthermore, in any one of the conditions mentioned the circumstances may be such as to require prompt removal to some institution.

If there is a removable cause and a prospect of early relief, it would be better to arrange for the care of the patient at home; to prepare a room, with screens at the windows, and secure one or more nurses, and endeavor to tide the patient over the attack. These arrangements may be made at a neighbor's house, or at the physician's house, or in any private house or sanitarium. Some of these patients may also go among relatives or travel without serious risk. In all of such cases, if possible, advice should be secured of some one having extensive knowledge of insanity. The pecuniary means and resources of the patient also enter largely as a factor in determining whether or not he can be treated at home.

If the patient is sent away there may be a choice between public or private hospitals, sanitariums, etc. Many patients require as a first requisite a total change of surroundings, and this may be secured without sending them to public hospitals.

When patients are kept at home certain adjuncts to their treatment may be useful, as baths in various forms, and massage. Shampooing of the head is often very soothing. A thing that renders home-treatment now more feasible is that there is an increasing body of skilled nurses and attendants becoming available. Many of the institutions for the insane have training-schools, and send out with the classes of their yearly graduates many well-qualified nurses and attendants, and the trained nurses and attendants of the general hospitals also can often be secured. If the patient is in good physical condition a large amount of exercise may be taken, to the point of physical fatigue, and better rest and sleep thus be secured. In all cases, patients should be largely kept in the open air, if their condition will admit of it, and sometimes to secure sleep at night a glass of milk-punch, or some malt liquor, will be more efficacious than large doses of hypnotics, and the after-effects will be less harmful.

Second. The next question has reference to keeping patients at home improperly. The reluctance of friends to send the patient away is often so marked that it must be confessed that there is more danger of improper detention at home than of premature sending to a hospital. The opposition of the patient or of friends in this respect is at times unreasonable, and at other times quite reasonable, and this point needs careful weighing. The advantages at home have been mentioned, personal care and the presence of family and friends, but there are certain cases in which these are injurious. Many patients are quite obstreperous and unmanageable with their own family and friends, who are easily cared for by judicious strangers.

Some patients must absolutely go to the hospital. Most cases of acute mania, of epileptic insanity, and of agitative melancholia, come under this head; also those who are excessively noisy, filthy, destructive, or have perverted instincts.

The cases in which the family and friends of the patient are not likely to give good care to the patient are those of hysteria and nervous prostration, in which the friends are over-sympathetic, and too much governed by the unreasonable fancies of the patient; and, on the other hand, if there is an overbearing and arbitrary disposition on either side, with irritable temper, cruelty may result. Another risk of not sending patients away is that their own family and friends, especially neurotic persons and children in the family, may be injured by the presence and contact of such persons in immediate daily intercourse.

Third. In considering the course to be pursued in case patients are treated at home, the following points should be taken into account: To secure, where it is available, expert advice; to avoid excessive use of drugs. Drugs form the smallest part of the treatment oftentimes, as it is the general surroundings and hygienic management, and the influences of a social, moral, and intellectual kind, to which we must look for benefit.

If patients cannot be kept at home without protracted stupefaction by drugs it is better to send them away. Hypnotics and sedatives should in general only be given at night, and the patient should through the day be free from their effect. If the patient is in good physical condition, a good deal of sleep may be lost in the early stages without serious harm.

[1] Alienist and Neurologist, vol. ii (1881), p. 28.

Nurses or attendants, one or more for day or night, or both, will generally be needed, and a room properly arranged for the care of the patient.

A constant lookout should be kept for the development of any dangerous tendency. Some frightful tragedies have occurred in the cases of patients treated at home, even in the practice of noted and experienced specialists engaged largely in this line of practice.

In dealing with patients, common sense must be applied to all that is done. The unreasonable whims of the patient should not be yielded to, and yet his harmless fancies should be gratified as far as may be possible and for his good. In some cases, it is especially important to avoid undue sympathy, and in others any harsh or arbitrary thwarting of the wishes of the patient may be harmful.

The question of application of any means of mechanical restraint, such as strait-waistcoats, muffs, wristlets, mittens, etc., often becomes an urgent one. It may be stated, as a general rule, that a case which cannot be managed at home without such means should be sent to the hospital. It will be a matter of exceeding rarity that anything of this kind need be employed under judicious management in an institution, and the resources of the institution for avoiding their use are far greater than those of a private house. Every possible resource should be exhausted before applying anything of this kind.

In conclusion, a word of advice as to the method to be adopted in case it becomes necessary to send a patient to the hospital. In dealing with the patient a frank and straightforward course should, under all circumstances, be pursued. One of the most vicious tendencies of the friends of patients and of those generally who have had no experience in this line is to conceal the truth from patients, to fall in with all their whims, delusions, and vagaries, as if they were believed in; to promise them everything they ask without any thought of keeping the promise; to tell them falsehoods, *e. g.*, that you do not believe them to be insane; that if sent to the hospital they are going to a first-class hotel to board, and have everything their own way; that if they go to the hospitals they are only to stay a few hours or days at most. All these methods of deceiving patients are injurious and harmful in a high degree. Patients should not be taken to the hospitals by deceit. Of the two, force is preferable to deceit. It is rare, however, that any patient who would be manageable under any circumstances would not be more so by being dealt with frankly and rationally, but kindly.

In conclusion, one guiding principle may be emphasized, which is more needed than any other in dealing with the insane, namely: To treat them as nearly as the conditions of their insanity will allow, in the same way that we would treat a rational fellow-being or wish to be treated ourselves.

SUGGESTIONS ON THE TREATMENT OF EARLY SYPHILIS.

BY ALFRED EICHLER, M.D.,
PHYSICIAN TO ST. JOSEPH'S HOSPITAL, SAN FRANCISCO, CAL.

AMONG the advances in therapeutics that have not been generally adopted by the medical profession should be mentioned the use of hypodermatic medication in syphilis. To one who has experienced in actual practice the faults and disadvantages of antisyphilitic medication by the mouth and by inunction, it is almost astonishing that so few general practitioners, not to speak of specialists, have taken up the subcutaneous method. Although I have employed injections of soluble mercurial salts only during the last two years, I have already become so thoroughly convinced of the utility and the advantages of the method that I desire to call further attention to its application.

One of the reasons why subcutaneous injections are not more frequently practised is, perhaps, that so many different agents, or rather salts of mercury, have been advocated for the purpose, with claims of special excellence for each one, as to almost confuse the uninitiated. The salicylate, thymolo-acetate, cyanide, benzoate, albuminate, and peptonate are the soluble preparations of mercury most often suggested, while among the insoluble, gray oil, the mild chloride, and the oxides seem to have the preference.

I have used the salicylate in only one case, and have found it not to possess any advantages over corrosive sublimate, which I have injected in all of my other cases, now some fifteen in number. I have always used corrosive sublimate in the solution suggested by Bartholow:[1]

℞.—Hydrarg. chlor. corros. . . gr. j.
Glycerin. } . . . . ãã ʒj.—M.
Aquæ }
Ten minims contain gr. $\frac{1}{12}$.
S.—Inject ten minims daily.

I have injected this amount daily, always with the rigid antiseptic precautions, usually between the shoulder-blades or into the gluteal region. With the exception of my first case, I have never had difficulties of any kind following the injections—a fact that I attribute mostly to the antisepsis practised, as well as to the depth of the injections.

I found it necessary, however, from the outset to discard the ordinary hypodermatic needle. Instead I employ a thin, slender needle, not more than two inches long, such as are sold by instrument-

[1] Materia Medica and Therapeutics, p. 254.

dealers to morphine-habitués who practise hypodermatic injections. Injections with this needle cause almost no pain if the fluid is thrown sufficiently deep. Of course, it is necessary to have a number of needles on hand, as they often become clogged from the corroding action of the sublimate solution on the metal; if treated properly, however, by cleaning with warm water, and drying thoroughly after each injection, a needle will last for at least a half-dozen injections.

I wish to dilate somewhat on the plan of treating syphilitic patients that I usually employ. All of my patients of this class are private patients, and are therefore more easily controlled and better managed than migratory and unreliable dispensary or hospital out-patients. They are commonly seen shortly after the appearance of the primary lesion, and are then kept on some placebo, given, perhaps, with a view of regulating the bowels or quieting a disturbed digestive tract, until the appearance of a rash or other decisive symptom confirms the diagnosis of syphilis. During this time, the initial lesion is dressed once a day with an application of equal parts of mercurial plaster and carbolated vaselin. If the sore presents a mixed character, *i. e.*, if it partakes of the characteristics of chancroid, and is deprived of a mucous covering, with secretion of pus, an ointment of iodoform and vaselin (1 : 4), scented with oil of rose, is prescribed to be applied twice daily. The patient is instructed to call at least twice a week, and is examined thoroughly each time. After the primary lesion has healed, he has to call once a week until the rash has appeared. According to my notes, the earliest eruption occurred after the fourth week, and the latest after three months.

As soon as the eruption is seen, hypodermatic injections are begun. The patient calls daily at an hour agreed on, and receives an injection containing one-twelfth of a grain of corrosive sublimate, and five minims each of glycerin and water. I use a separate needle and a separate solution for each patient. The solution must always be kept perfectly clear. Before giving the injection, the back is wiped with absorbent cotton saturated with ether, over an area about five inches square, to remove perspiration, etc.; then a 5 per cent. solution of carbolic acid is applied by means of an absorbent cotton sponge; after the skin is thoroughly dried, another pledget saturated with pure ether is applied to the point at which the needle is to be introduced, thus temporarily producing a local anesthesia. The injection is then made by quickly introducing the needle deeply, until muscular tissue, or at least the deeper layers of cellular tisue, have been reached; the more remote from the skin the contents of the syringe are deposited the less the pain afterward experienced by the patient. The local anesthesia produced by the ether is sufficient to prevent the patient from feeling the injection, and often after the needle has been withdrawn have I been asked whether I had already injected. The injections are repeated daily until twelve have been given, representing a total of one grain of corrosive sublimate. They are then discontinued for one week. After that time, they are repeated daily until twelve more have been given. After the second twelve, I discontinue for another week, and then give the final twelve, making thirty-six in all. In a few instances of evidently very mild syphilis, I have omitted the third dozen. Ordinarily, however, I insist upon the full number of injections. It is astonishing how rapidly skin-symptoms disappear under this treatment. I have seen a marked syphilide subside after the third injection, so that by the last injection of the first twelve not a trace was noticeable. Mild eruptions have usually faded away by the eighth day. In a case of syphilitic alopecia, the hair began to grow after the eighth injection had been given, and within a month no bald spots were noticeable.

During all this time, I have the patient pay the strictest attention to his mouth. It is often stated that corrosive sublimate does not produce salivation as quickly as other mercurials; but then, as the absorption of the drug by the hypodermatic method is very rapid, I have always thought an ounce of prevention to be better than a pound of cure, and have abstained from determining the truth of the statement by actual experiment.

I prescribe for every one of my syphilitic patients a toothpowder composed of

℞—Potass. chloratis, }
Pulv. aluminis, } . . . āā ℥j
Sacchari lactis, }
Pulv. kino, ... ℥j
Ol. menth. pip., . . . q. s.—M.

with instructions that it be freely used after every meal, with plenty of water and a not too hard toothbrush, at the same time suggesting frequent washing of the mouth with pure cold water.

I have thus far had no mercurial stomatitis to treat in my patients subjected to hypodermatic injections of soluble mercurial salts.

Recognizing that syphilis is a disease preëminently undermining the constitution and deteriorating the blood by the action of a special virus, I try to supplement the mercurial treatment by hygienic measures that aid in sustaining vital force. I request every one of my patients who does not lead an outdoor life to take a daily tramp of at least four miles, consequently of more than an hour's duration, preferably in one of the parks or along the bayshore. I further insist upon one point, and I think this more essential than the first: frequent baths, at least

three times a week, when not under treatment, and daily when injections are given. Cold-water baths, or at least water as cold as can be borne for fifteen minutes, is preferable; for swimmers—and the large majority of my patients were swimmers—I suggested open-air baths in the bay, even if the water was cold. After the cold bath, a walk of not less than fifteen minutes' duration should be taken.

I interdict alcoholic liquors entirely for those who have used them moderately; those accustomed to taking large quantities, especially of the stronger spirits and of beer, are ordered to limit themselves to claret and similar light wines. I believe that it is good practice during the taking of a mercurial course of any kind to relieve the excretory apparatus of all useless burdens, of which alcohol is certainly a considerable one. Further, as a majority of this class of patients are high livers, a temporary abstinence can only prove of benefit to them.

I have achieved success with this plan. The mercury subdued all symptoms promptly, while the physical exercise helped to build up the body materially. Almost all of my patients gained much in weight and strength. The physical appearance often changed rapidly. The skin, which had been rendered muddy by the protracted town-life and excesses in living, became clear and clean again; adipose tissue increased, and the patients became more robust in appearance. None of my patients has thus far needed more than thirty-six injections. As I have had none under observation for a longer time than two years, I may, perhaps, be somewhat rash in claiming unusual results for this plan of treatment.

Compared with other methods of treament—inunctions, the pill of the protoiodide, and Gibert's syrup—I claim that in all of my cases I have only noticed mucous patches in two instances, whereas previously to employing the hypodermatic method it seems to me that almost one of every three presented throat-lesions. Both of the two cases in which manifestations of syphilis reappeared, were engaged in the liquor business, and were perhaps exposed to greater temptations in the way of alcohol than the others. As their cases seemed mild, both had received only twenty-four injections, and under proper local treatment, gargling with solutions of potassium chlorate, and repeated applications of silver nitrate, and an additional dozen of injections, all lesions disappeared, and the patients have remained free since. In one, mucous patches had appeared in the fourth month, after the twenty-fourth injection, while in the other it was almost eight months afterward. Both have now been free for more than six months..

In none of the other cases have recurrences thus far been noted, and they are all yet under observation. None of my patients ever objected to hypodermatic medication, after the advantages and the promptness of the method had been fully explained. While there exists among certain classes a great prejudice against the hypodermatic syringe, mostly from fear of forming a habit, as soon as it is explained that all injections are given by the physician himself, that only a limited number is required, and that certain results can be quickly arrived at, then all objections on the part of the patient vanish, and in a short while he is more than pleased not to be compelled to swallow pills and mixtures, or even grease himself, but to be finished with all medication after he has paid his morning or evening visit to his physician. The latter also derives great benefit from the adoption of the hypodermatic method. In the first place, he has absolute control of his patient, thus gaining a point of great importance. Then, he employs accurate and exact dosage, as the injections are administered by himself, and there is no excuse for forgetting pills, etc. Further, there is more rapid absorption, and also excretion, than when either inunction or internal medication is employed, and consequently a more rapid disapearance of symptoms and local lesions. The alimentary canal is not disturbed at all; there is no diarrhea, as with the protoiodide or the tannate; there is less tendency to salivation than when inunctions are used, while the measure is more cleanly; finally, the proportion of relapses is, in all probability, diminished in comparison with other therapeutic methods.

The only requisites to a successful application are perfectly clear and properly concentrated and prepared solutions, absolute antisepsis, and deep injections with a fine needle, the further from the skin the better. I have never had any evil consequences, such as abscesses, except in my first case, in which I used an ordinary hypodermatic needle, and caused a good deal of pain, and set up a slight cellulitis by failing to inject deep enough. Since using the finer needles, and making deep injections, I have had no trouble and have caused no pain after the injection.

In the treatment of the later lesions of syphilis, I have not had much experience with the hypodermatic method, as a course of the iodides usually proves very efficient. I remember, however, one case that was sent to me. The patient, a young woman of doubtful character, had contracted syphilis about a year previously, and had been treated by a physician with pills of the protoiodide, taking as much as six grains in a day. After taking these for three months she thought herself cured, and omitted them until she began suffering from sore-throat. On examination I found a mucous patch on the soft palate almost as large as a half-dollar.

She received an injection of the sublimate daily for twelve days, with applications of silver nitrate, and after the eighth day nothing could be noticed in her mouth. This proved to me conclusively the effectiveness of the hypodermatic injections.

It has been suggested by some authors that a large quantity of mercuric chloride, say about a quarter of a grain, be injected into the buttocks once a week. I have always preferred to inject smaller quantities daily, even at the risk of causing a little more trouble. I believe that the small doses, frequently repeated, are more rapidly absorbed and excreted, and consequently exercise their effect sooner and more continuously than the large doses given only occasionally.

With injections of insoluble mercurial salts I have no experience. I have never tried them, and consequently my objections are based only on theoretic grounds. My first objection is that an insoluble preparation has to be converted by the action of the body-tissues and fluids into a soluble compound, and therefore I cannot comprehend why one should not inject a soluble compound at once. Another objection is that by reason of their insolubility they must be absorbed only gradually (during their residence in the tissues they are practically foreign bodies, therefore irritants). Although this slow absorption might at times be a desideratum, it is ordinarily a great obstacle, for, if symptoms of mercurial poisoning should arise, there would be no way of removing the injected mercury and all treatment directed to relieving the condition would be futile.

I might mention that when corrosive sublimate is injected beneath the skin, a hard nodule usually forms, which does not disappear for about a week; this is caused by the coagulation of the albumin by the sublimate, resulting in a hardening of the tissues, which, however, produces no ill results; in a week it is absorbed. When several injections are made at points close together, considerable tension occurs, from the pressing of the hardened tissues on the skin. This explains the weekly interval between each dozen of injections. The tension can, however, be easily relieved by the application of some softening ointment, rendering the skin more pliable. Tincture of iodine proves effective by stimulating absorption. When the injection is made deeply, preferably into muscular tissue, the consequence is insignificant, as the pressure and tension of the skin are relatively small. It is also wise to select for injection such parts of the body as are not subject to pressure from clothing, etc.

In giving thirty-six injections I have only attempted to set down a definite number, sufficient for ordinary cases. Whether this will prove enough in all cases for an eradication of the virus and subsequent immunity is a question that only time can settle.

A PLEA FOR SPECIAL STATE PROVISION FOR EPILEPTICS.[1]

By THEODORE DILLER, M.D.,
FELLOW OF THE PITTSBURG ACADEMY OF MEDICINE.

All who have dealings or are brought in contact with epileptics, either in a professional, business, or social way are, I am sure, impressed by the peculiar misfortune of these poor sufferers. It is indeed a cruel irony of fate that the wretched epileptic usually knows not when or where or in what manner he will succumb to an attack; that he knows not what fright, consternation, or distress his fit will bring to those about him at the time of its occurrence. His future is always uncertain; neither he nor his friends can ever tell just when, where, or how his plans may be interrupted. A lady who is an epileptic and whose fits occur rather infrequently, once told me that she would be well satisfied if they were to occur many times as frequently as they did, if she could only have ample warning of the approach of each seizure, so that she might be spared the frequent humiliation of creating a scene. True, some more fortunate epileptics experience auræ sufficient time before a seizure to seek a place of safety and retirement. Then, too, there are those whose fits occur so infrequently as not to create a very serious break in their life's work; again, there are those whose attacks are always of the *petit mal* variety. But it is not for these last-named types of epileptics that I want specially to make a plea before this Society. It is for the epileptic whose fits are frequent and violent; whose mental balance is shaken; for those who are either friendless or poor, or both; for those who are in the hospitals, asylums, or almshouses of the State, or in wretched homes. In making this plea for the epileptics in our asylums and hospitals, I also make a plea for the other patients in these institutions who are compelled to be kept associated with them.

The mental aberration in the epileptic varies from an almost inappreciable deflection, through many shades, up to the most pronounced dementia or violent frenzy (which last-named state is one of the most dangerous seen in asylums).

Generally speaking, only those epileptics whose fits occur very frequently or with great violence, or whose mental alienation is rather pronounced, are found in our general hospitals or insane asylums. Many epileptics are, however, in institutions who would not be there at all were their relatives so situated that they could be cared for at home.

In 1890, there were in the various State insane

[1] A paper read at the forty-second annual session of the Medical Society of Pennsylvania, at Harrisburg, May 17, 1892.

asylums, almshouses, etc., throughout the Commonwealth, under the jurisdiction of the State Committee of Lunacy, 615 epileptics, the great majority of whom were indigent. These, together with those in general hospitals, would probably foot up a total in institutions of over 1000. There are probably 4000 or 5000 epileptics of all grades living in Pennsylvania.

On account of the great variation in the degree and nature of the symptoms of these patients, they are in most of the hospitals for the insane distributed through nearly all of the wards according to their general mental condition and the frequency and character of the seizures. An epileptic whose fits occur infrequently, and whose mental condition during the intervals between attacks is good, is placed in a ward with the quieter patients, some of whom are convalescents. It would seem almost cruel to compel him to remain in a ward with the violent or chronic insane. The companionship would be a constant source of depression to him; yet, placed in wards in which he is more nearly on a par with his fellow-patients, while advantageous for the epileptic, is bad for the other patients in that ward. For the fit, though perhaps infrequent, comes, causing distress and excitement when it does come. Who is there among the laity, unaccustomed to the sight of an epileptic fit, who is not greatly shocked in the presence of one? Who, then, can tell the back-set which a patient convalescing from acute insanity may not receive from witnessing such a painful and revolting manifestation as an epileptic fit?

In some of our general hospitals a separate ward is provided for epileptics. This plan possesses the great advantage of sparing the non-epileptic patients the pain of witnessing epileptic fits; but it is unfortunate in that it compels the epileptic who enjoys the possession of nearly all of his mental faculties and whose fits occur infrequently, to associate with the epileptic dement who has many seizures daily.

If all of the epileptics now inmates of institutions in the State were to be removed from them, I am sure the patients remaining in these institutions would be much benefited; besides this, the management of these institutions would be not a little simplified. By placing the epileptics so removed in a pleasantly located hospital, specially equipped for their care, where they could be properly classified, they too, in turn, would be much benefited.

There are now so many different hospitals built with respect to accommodating various classes of patients that it seems strange that almost nothing has been said or done in this country for special provision for epileptics. We have the hospital for women; one for children; one for opium-habitués and alcoholics; one for nervous diseases; one for the acute insane, another for the chronic insane; one for the criminal insane; another for those suffering from tuberculosis; still another for those suffering from carcinoma. Yet the epileptic, whose disease is, in a peculiar way, a special disease, has no special hospital provided for him in the United States, with the single exception of Dr. Baker's institution at Baldwinsville, Mass. The subject has, however, been agitated in at least two States—New York and Massachusetts.

On the other side of the Atlantic the epileptic has fared much better; for in Europe we find special hospitals provided for him in France, Holland, Switzerland, Sweden, and Germany. It is in Germany, however, that the principle of separate care and treatment of the epileptic has made most progress; for in Germany there are no less than ten institutions whose sole mission is the treatment and care of epileptics. Probably the most notable of these institutions is that at Bielefeld, near Hanover. The medical profession should feel ashamed that the necessity of separate provision for epileptics was not only first recognized by a layman—the earnest, thoughtful Lutheran pastor, Von Bodelschwingh—but also received from him the first practical impetus which, twenty-five years ago, laid in a small way the foundations of what is now the great and wonderful colony of Bielefeld. This thoughtful, pious, philanthropic clergyman not only recognized the special and peculiar needs of epileptics, but he set about providing for them in a way that may well excite our admiration. Of course, much was learned by experience as the colony grew; of course, much was done that had to be undone, and many methods of dealing with patients that promised good results proved disappointing. The colony has, however, been so well planted; it has been so well shaped and nurtured; it is so well managed and equipped, that it may be seriously questioned whether we could to-day start a plant in Pennsylvania which would in any material or essential way improve upon it. From a beginning of twelve patients, twenty-five years ago, there are now upward of 1000 in the various departments of the colony.

The plain, simple, effective manner in which the colony is managed may well excite emulation. There are no great, tall, foreboding "institutional" buildings; but instead, many small buildings adapted for the various grades of patients. The ample grounds give opportunity for as much agricultural employment as the patients can manage. Provision is made for many different occupations, such as printing, brick-making, iron-working, shoemaking for the males; and tailoring, weaving, and domestic work for the women. The whole general appearance of the colony is rather that of a peaceful village than that of a hospital.

The advantages of the essential features of this colony will, I believe, very generally receive the approbation of those most extensively acquainted with epileptics. These features may be briefly summarized as follows: 1. The lack of institutional character in the buildings and the near approach to ordinary village or rural life. 2. The opportunity for the extensive classification of patients. 3. The ample provision for engagement in many and diverse occupations, so that all physically qualified can find work suited to their respective tastes and abilities. 4. The provision for the most favorable hygienic conditions; the best moral and therapeutic measures; and the best mechanical appliances, such as special low beds, etc.

These features ought all to be incorporated in the hospital or colony which, I trust, our State will, ere long, cause to be established.

What sort of cases ought a special hospital or colony of this kind to receive? Of course, it goes without saying that very many epileptics who possess a high degree of intelligence and are but infrequently disturbed by seizures, need no State care of any sort. Napoleon and Julius Cæsar afford remarkable examples of the achievements possible for the epileptic. Then, too, there are the epileptics who are in comfortable circumstances financially and who have many friends. These will be loath to enter an institution, and they are in most instances in good position to be cared for privately. The institution should be established primarily to provide for indigent epileptics. Provision ought also be made for the admission of pay-patients. Indeed, it might even be well to provide special accommodations for patients of this class upon payment of ample rates, provided such care would not be a detriment to the colony or to any other patients in it. I am not sure, however, that the well-to-do would not be better off in a separate institution under private management.

One very important matter in connection with an institution of this kind would be the legal status of the patients. It would be quite necessary, at least for the majority of the patients, that they be detained legally, much in the same way as the insane are now detained. Provision might, perhaps, be made for voluntary patients, somewhat after the fashion of the new Massachusetts lunacy law. The necessity for such power on the part of the institution must, I think, be apparent to all who are much acquainted with the whimsical and erratic nature of the class of epileptics that would enter such an institution. They are very prone to take umbrage without cause and to be greatly offended or slighted by little or no provocation. Then, too, there occurs in some the highly dangerous and totally irresponsible period of the so-called post-epileptic state. During these highly unstable mental states patients would often leave the institution, just at the time when they most needed its care, if there were no legal provision for their detention.

I am not prepared at this time to submit specific plans looking to the carrying out of the scheme that I have thus broadly presented to you. I trust, however, that a full and free discussion will follow, and that the Society will vote in the end to present a petition to the Legislature asking it to take measures to provide for such an institution as I have here advocated.

THE METRIC SYSTEM.[1]

BY A. L. BENEDICT, A.M., M.D.,
OF BUFFALO.

A SYSTEM of weights and measures is to the physician what a system of money is to a business man —a useful and necessary adjunct, upon the convenience or inconvenience of which much depends, and which is not, on the one hand, defective, a barrier to success, or, on the other hand, perfect, a substitute for genuine business or professional ability. Our decimal system of money has doubtless saved the merchants of our country thousands of dollars in the value of their own time, in clerkhire, and in lessening the liability to error in arithmetical computations, but we can scarcely say that a man is any shrewder in estimating values or, in general, any more successful in business because he calculates in dollars and cents instead of pounds, shillings, and pence. It certainly would be sheer nonsense to criticise a physician's intelligence or power of combating disease on the ground that his units of measurement were not in accordance with the highest scientific usage. I advocate the metric system of prescribing, therefore, with precisely the same feeling as I would advise the adoption of an improved instrument or a more convenient method of keeping accounts.

The advantages of the metric system over the apothecary's are: 1. The ease of computation characteristic of any decimal system. 2. The scientific and exact correspondence between the units of volume and weight, in contrast with the approximate relation of the minim to the grain. 3. The fact that those using the metric system are in harmony with the majority of scientific and medical men the world over; it must be remembered that our apothecary's system is only approximately related to that in use in the British Empire. 4. The provision of units capable of expressing small quantities, without recourse to fractions. These advantages are so plain and they have been so

[1] A paper read before the Erie County, N. Y., Medical Society, embracing a report as chairman of a committee appointed to investigate the practical use of the metric system.

widely discussed that no more time need be devoted to them, but I shall take up more at length some of the objections that have been urged against the use of the metric system.

1. The adoption of the metric system would necessitate the unlearning of that with which the majority of the profession are familiar, and would require additional exertion in learning a substitute. This is the same irrefutable argument that was urged against our decimal monetary system and which has been brought to bear against every effort at reform that has ever been proposed in any branch of human activity. It should be remarked, however, that, at present, nothing more is asked than that the metric system be adopted in connection with the apothecary's. Every physician knows that, except in reading or listening to the thoughts of other men, he may be almost absolutely independent of everyone else in his prescribing. We must also bear in mind the fact that it is one thing to attempt to change the familiar habits of thought of a whole people and a much less formidable affair to undertake a similar change in a comparatively small body of men whose average intelligence and progressiveness is much above that of the mass of the people.

2. It is said that the use of the metric system is liable to bring about errors, both in writing and in compounding prescriptions. As to the former, blunders depend more upon the carelessness of individuals than upon the peculiarities of any system of nomenclature or numeration. Aside from the danger of mistakes in dose that are as likely to occur under one system as under another, errors in writing the metric doses can occur only from misplacing figures with regard to the decimal point and from illegibility. The confusion of dram and ounce signs, the cutting off of X's into V's, and the running together of two I's into a V, are quite as great sources of error. The use of a ruled decimal line on prescription blanks is a safeguard against false alignment. As to the second danger, that of mistakes on the part of the druggist, I have found this quite an imaginary one in Buffalo. Most pharmacists are perfectly competent to fill metric prescriptions, and, throughout the country, the colleges of pharmacy are far more progressive than are the medical schools in requiring a theoretical and practical acquaintance with the metric system on the part of their students.

3. A gentleman who, from his official position, was required to use the metric system, and who, from personal prejudice, made this use a purely nominal one, offered this objection, that prescriptions written in the metric system would leave an empty space in the bottles prepared for a given number of ounces. This reminds me of the anecdote of the shoemaker who apologized for a pair of misfit boots on the ground that if the customer would cut off his corns, probably the boots would be a perfect fit. To this suggestion the customer replied that he did not propose to plane his feet to the dimensions of any pair of boots. I must confess the same kind of egotism in regard to my prescriptions; but even from the practical and common-place view, there is no reason for a misfit occurring between the prescription and the bottle. There are already on the market bottles graduated to a convenient number of cubic centimeters, and I am informed by a pharmacist that one hundred cubic centimeters, the usual twenty-dose mixture, is a proper amount for a four-ounce bottle, leaving no more space at the top than should be allowed for thorough shaking.

Your committee has, informally and without much attempt at thoroughness, canvassed the local profession, comprising some two hundred and fifty regular practitioners, to ascertain the number and influence of those who use the metric system of prescribing. We are personally acquainted with about fifteen who use this system to the exclusion of the other, except in rare instances when commercial reasons or the necessity of particular caution may indicate the use of the older terms. Quite a number of other physicians use the metric system to some extent, and there are many others who would gladly do so were it not that they hesitate to leave the beaten track. Your committee has estimated that about thirty thousand prescriptions are annually written in the metric system in the city of Buffalo. It is also, nominally, in exclusive use at the Buffalo General Hospital, and this use at times becomes actual, as well as nominal, according to the views of the visiting and the house staff. At the Fitch Dispensary about a fifth of the patients are prescribed for in the metric system. It is in use at the United States Marine Hospital Office and in the marine ward of the Sisters' Hospital, at the Buffalo Eye and Ear Infirmary, and in part at the Ingleside Home Hospital.

ORIGINAL LECTURE.

EMBOLISM OF THE LEFT CORONARY ARTERY; SUDDEN DEATH.[1]

BY LUDVIG HEKTOEN, M.D.,
PATHOLOGIST TO THE COOK COUNTY HOSPITAL, CHICAGO.

LADIES AND GENTLEMEN: The man whose body we are about to examine was thirty-two years old when he died suddenly, about sixteen hours ago. He was a carpenter by occupation, and had commenced his usual work yesterday morning, but he was soon obliged to stop; he was assisted to the sidewalk by two men, and, complaining of intense pain in the chest, he was placed

[1] Report of the post-mortem examination made before the class in the Cook County Hospital Dead-house, May 17, 1892.

in the police ambulance and hurried off to the hospital, on the way to which he died.

This is all of his history that is known.

Inspection shows a well-nourished, muscular man, without any marks of bodily violence; there is marked lividity of the posterior aspect of the body, extending up to and including the ears; rigor mortis is quite decided.

Internal examination. — The abdominal cavity is empty; the peritoneum is smooth and shining; there are firm adhesions around the spleen, and also between the gall-bladder and the hepatic flexure of the colon. The diaphragm reaches to the fifth rib on either side. The pericardium contains the usual quantity of clear, yellow fluid; it is quite smooth, but the epicardium is thickened and grayish in color over the greater surface of the heart, but not more so in the vicinity of the coronary vessels than elsewhere. Both pleural cavities are partially obliterated by quite firm adhesions, and contain no fluid. The right side of the heart contains a moderate quantity of dark-red, fluid blood; the left side is practically empty. The semilunar valves are quite competent to the water-test. The endocardium of the right heart is normal; the tricuspid orifice admits four or five finger-tips readily; the cavity of the right ventricle is 8 cm. deep, and its wall is 4 mm. thick. The endocardium of the left heart is also nearly normal, there being a few yellow areas in the anterior segment of the mitral valve, the free margins of which also appear to be a little thickened; the mitral orifice admits three finger-tips; the cavity of the left ventricle measures 8 cm. in depth, and the wall is 1 cm. in thickness. In the myocardium of both ventricles are seen small, white areas and streaks, scattered quite freely over every cut surface; there are no areas of softening. In the aorta there are a few yellowish-gray areas, of irregular outline and size, extending from the valves down to the diaphragm, and occupying in the thoracic aorta a strip about 5 cm. wide that includes the orifices of the intercostal arteries; there is no very marked thickening of the intima, the yellow areas being situated in its upper layers. At the origin of the large vessels at the root of the neck the intima presents distinct scars; situated upon the wall of the aorta, just above the junction of the anterior with the left posterior aortic leaflet, is a wart-like mass, measuring about 4 mm. in height and 3 mm. in diameter, that appears to be composed of fibrin; it is quite firmly adherent to the wall of the vessel, and is a parietal thrombus in the aorta. On slitting up the left coronary artery I come upon a quite firm, grayish, granular mass that completely occludes the lumen of the vessel, to the walls of which it is not adherent, lying just in front of the bifurcation of the artery at the commencement of the anterior inter-ventricular groove. This mass is, in all probability, an embolus that has lodged at the bifurcation of the left coronary artery.

In the coronary arteries are seen many areas of yellowish thickening in the intima, but none of these areas is rough or covered with thrombi, the lumen of the vessels being practically of normal size, except at the point mentioned, where it was completely obliterated.

The lungs are heavy and soggy, and contain much blood and frothy fluid.

The spleen presents a considerable area of thickening of its capsule; the area is 6 cm. long, 2 cm. wide, and at the thickest portion it is nearly 1 cm. in thickness; it is fibro-cartilaginous in consistence, and quite uniformly yellow on the cut surface. In the splenic substance, which is rather soft, but otherwise like the normal, are two areas that consists of caseous, granular material inclosed in a dense, measurably thick, homogeneous capsule; one of these areas measures one, the other one one-half cm. in diameter.

The left kidney is 12 by 6 by 3 cm. in size; the capsule peels readily; the surface is smooth and the cortical markings distinct on the cut section, the labyrinths presenting plainly visible and prominent glomeruli, because the latter contain much blood; the kidney is quite firm, and blood runs quite freely from the cut surface. The pelvis of the kidney is normal.

The right kidney is of about the same size as the left; the capsule peels quite readily; the surface is smooth, but presents numerous areas of a light-yellow color, of irregular outline and varying size; on section these areas are, in each instance, seen to correspond with anemic infarcts in the kidney. The kidney contains altogether eight distinct, wedge-shaped areas, which have a uniform, light-yellow color, are bloodless, have a red line at their periphery, the base of the wedge lying upon the surface of the kidney, the apex in the smaller infarcts being situated within the cortex, in the larger ones down in the columns of Bertini; the smallest infarct has a base measuring 3 mm.; the largest has a base measuring 2 cm. in greatest diameter. The kidney is otherwise quite normal.

The bladder, seminal vesicles, prostate gland, and testicles present no abnormality. The liver and the gall-bladder are also apparently normal. The mucous membrane of the stomach is covered with a viscid, grayish, turbid mucus; it presents many folds and elevations—so that in places it is almost distinctly nodular; the folds are not obliterated on stretching the muscular coat, and the gastric mucous membrane rises above the esophageal at their junction—it is consequently thickened. The pancreas is normal.

There is no fracture of the skull; the membranes are smooth and shining; there are no areas of thickening in the pia, which is not abnormally adherent. The ventricles are empty; there are no changes, no thrombi, no emboli in the vessels at the base, and after the usual section of the brain we cannot discover any foci of old or of recent softening.

The anatomic diagnosis will consequently read: Chronic deforming endarteritis of the aorta and coronary arteries; parietal thrombosis of the aorta; embolism of the left coronary artery; chronic fibrous myocarditis; anemic infarcts of the right kidney; congestion of the left kidney; chronic gastric catarrh; chronic fibrous perisplenitis and pericystitis; gummata (?) in the spleen; chronic pleuritis; pulmonary edema and congestion.

Remarks.—It can be quite safely stated that our examination has demonstrated the cause of this man's death, namely, embolism of the left coronary artery. This would cause anemia of almost the entire left half of the heart; a collateral circulation could not be established, because the coronary arteries belong to the so-called terminal arteries, and death would consequently ensue from cardiac paralysis before any consecutive degenerative changes in the myocardium could have time to become

apparent. The source of the embolus was, undoubtedly, the thrombus in the aorta from which fibrinous masses might at any time have been washed away with the blood-current. The thrombus formed upon a rough spot, due to the degeneration and loss of substance incident to the extensive chronic endarteritis that was present in the commencement of aorta. From the same thrombus came also, in all probability, the emboli that, lodging in the branches of the right renal artery, gave rise to the formation of infarcts as described; the yellow wedges or areas are due to coagulation-necrosis following the anemia that was caused by the blocking of the renal arterial branches, which are also terminal arteries; each anemic infarct marks out the area nourished by the corresponding vessel peripherally from the seat of the obstruction by the embolus.

The edema and congestion of the lungs can, in this case, be easily explained by the weakness of the left ventricle, as compared with the right, during the last moments of life.

The hyperemia of the left kidney is to be looked upon as compensatory, the right kidney being rendered functionless to a considerable extent by the many areas of anemic necrosis.

The fibrous myocarditis resulted from the chronic disease of the coronary arteries, which, gradually reducing the nourishment of small areas of the heart-muscle, finally caused a complete degeneration of these spots and connective-tissue substitution.

The truth of the statement "that a man is only as old as his arteries" is shown indirectly by the findings in this case; had the patient not had atheromatous patches in his aorta, the thrombosis and secondary embolism need not have resulted. Not knowing anything about the man's history, we cannot form any definite idea as to the etiology of the endarteritis; we cannot say whether it is an instance of the not uncommon, prematurely early involutional degeneration, the man being only thirty-two years old, or is due to some of the causes usually mentioned in connection with this disease, such as lead, alcohol, overwork, or syphilis. We can say that it is not secondary to renal disease, because the kidneys were found quite healthy, with the exception of recent infarcts; alcoholism, syphilis, and other causes cannot, however, be excluded, and whether, with regard to syphilis, actual evidences of this disease were present or not, in the shape of the possible gummatous areas in the spleen, cannot be definitely settled without a microscopic examination.

Finally, remember that we have here an excellent illustration of death due to blocking of a coronary artery—one of the most common causes of sudden death. The blocking may, as in this case, be due to embolism; it may be due to thrombosis secondary to chronic disease of the coronary arteries, or it may be due to occlusion of the orifice of one or both of the coronary arteries in the aorta by atheroma in this vessel, with or without the formation of a thrombus at the very orifice. The latter mode of obstruction was well illustrated in a man, thirty-five years old, who died suddenly in the street, and whose body I examined a few days ago. All the organs were found to be apparently quite normal, except the aorta, which was atheromatous down to the iliac arteries; just at its very commencement the process was most extensive, resulting in the formation of a grayish, raised, annular area, 1 cm. broad, involving the coronary orifices, which were only as large as pin-points; the left was occluded by a small thrombus hanging over the opening. In this case the coronary arteries themselves were not diseased, and the myocardium was quite healthy, but pale-grayish in color.

In all cases of sudden death that come up for medico-legal investigation the coronary arteries should invariably be thoroughly and completely examined.

NEW DEVICES.

TREATMENT OF CRUTCH-PARALYSIS.

J. H. HUDDLESTON, A.M., M.D.,
ATTENDING PHYSICIAN, MEDICAL DISPENSARY, GOUVERNEUR HOSPITAL; ASSISTANT IN CLINICAL MEDICINE, NEW YORK HOSPITAL.

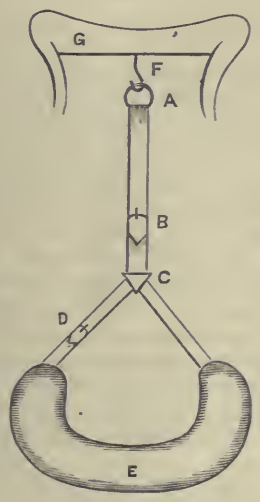
AMONG the unfortunate possibilities attending the use of a crutch, whether on account of a sprain, fracture, disease of joint or bone, or again, on account of a want of power in some muscles, is crutch-paralysis. For this, speedy cure can usually be obtained by rest; but too often the patient feels that he cannot rest, and sometimes the crutch, resumed after a rest, again causes paralysis. In prophylaxis, care in the selection of a crutch counts for much.

Krafft-Ebing[1] long ago pointed out that paralysis from this cause much less frequently occurs when the crutch is well-padded and has a grip so placed that when taken by the hand the arm is nearly straight. It is a not less important precaution to see that the crutch is sufficiently long, so that the body does not bend forward and rest on the great pectoral muscle exclusively. I have seen at least one case recover from the paralysis, with no other treatment than the exchange of too short crutches for a fit pair. With all care, however, paralysis sometimes comes on, or rather the ominous tingling of the fingers and slight weakness of grasp appear, and other means of treatment must be adopted. The cause of the paralysis is obvious: the body rests too heavily on the crutch, and the crutch presses too severely on the nerves. This is shown by the fact that the misfortune is more likely to occur in fat, elderly persons, and is exceedingly rare in children, though in these it does sometimes occur. If the body could be lifted partly from the support no injury to the nerves could occur. At the request of Dr. W. N. Bullard, of Boston, I sought a means of mechanical treatment, and I found the following practicable:

A perineal strap (E) is applied and fastened by a buckle (D) in front, so that the angle (C), at which the ends of the strap come together, shall be just above the crest of the ilium. At this angle (C) is a metallic triangle or ring, from the upper part of which ascends a suspensory strap of a length regulated by a buckle (B) to a ring (A). The perineal strap and the lower part of the suspensory strap (A C) go outside the underclothes and inside the outer clothes, but at the waist the upper strap passes, in women, outside all the clothes, while in men it is conducted under the waistcoast to the arm-hole, and out at that point. The upper ring (A) is then caught on a hook (F) screwed into the axillary bar (G) of the crutch. If

[1] Krafft-Ebing: "Krückenlähmung," Deutsche Archiv f. klin. Med., Bd. ix, 1872.

a pair of crutches is necessary, two perineal pads may be applied; if a single crutch is sufficient, one pad will give enough support. The suspensory straps must be buckled like suspenders at such a length that when the crutches



are in position, and the rings attached to the hooks, the axillæ feel no pressure, and the body rests on the perineal bands. When the patient sits, the ring can be removed in an instant from the hook and the crutch put aside, and when the patient again takes the crutch, placing the ring on the hook is also only momentary. All the straps must be inelastic, and may be made of either leather or webbing; if the latter, an inch is a good width. A large part of the success of the apparatus depends on the comfort of the perineal strap. This, when padded, should be large, smooth, and firm. One of the best of such straps is made of chamois skin stuffed with cork-dust; a cheaper form is made of canton flannel sewed into the shape of a sausage about a leather or webbing core.

A more complex pad that can be made comfortable for any one is that devised by Brackett,[1] which is usually made of leather lined with felt. Whatever form is used, the padded portion must be so long that no part of the seat is unprotected; any greater length is clumsy. Comfortable as the apparatus is when properly made, it is a trial to the patients who have to wear t, but it does, as I have found in four cases, accomplish its work; it keeps pressure from the axillary nerves, and insures speedy recovery.

A SIMPLE BOTTLE INHALER.

BY W. SCHEPPEGRELL, A.M., M.D.,
CLINICAL ASSISTANT TO NEW ORLEANS EYE, EAR, NOSE, AND THROAT HOSPITAL.

REALIZING the importance of medicated vapors in connection with the treatment of diseases of the lungs and respiratory passages, I have endeavored to devise an inhaler that, while effective, durable, and not likely to get out of order, could still be sold at a reasonable price.

The cheap inhalers are usually of little value, and the more costly ones are beyond the means of the poorer class of patients.

The device represented in the accompanying illustration fulfils the indications of an efficacious inhaler, and, on account of the simplicity of its mechanism, can be sold at a small cost. It is made for me by Messrs. Eimer & Amend, of New York.

It consists of a one-pint flask, closed by a rubber stopper having two perforations. In one of the perforations is passed a funnel tube to within a quarter of an inch of the bottom of the flask. Into the other perforation is passed another glass tube, one extremity of which extends an inch into the flask, the other extremity being bent at angle convenient for application.

For use, the flask is filled one-third with water or other diluent, warmed when advisable. The medicament, as tincture of iodine or eucalyptol, may then be dropped in sufficient proportion through the funnel tube. The patient then places the bent extremity of the tube in his mouth and inhales the air medicated by its passage through the solution in the flask.

When the solution loses its strength, additional medicament may be dropped into it through the funnel tube.

When it is desired that the mucous membrane of the nose and naso-pharynx should be also treated by the medicated vapor, a rubber tube and nose-piece may be attached to the glass tube of the inhaler, and the inhalations made through the nostril, to which the nose-piece of the inhaler is applied.

I have for some time, with much satisfaction, used inhalers like that described.

271 CARONDELET STREET.

MEDICAL PROGRESS.

Pachydermia Verrucosa Laryngis.—MEYER (*Berlin. klin. Wochenschr.*, No. 19, 1892, p. 454) has reported two cases of pachydermia verrucosa laryngis successfully treated by gradual excision. One was that of a man, fifty-three years old, who for two years had been hoarse, and for three months had suffered with marked and progressively increasing dyspnea. The right half of the larynx was found occupied by a chalky-white tumor, of cauliflower appearance and hard consistence,

extending beyond the median line and obstructing the view of the deeper parts of the larynx. The growth apparently originated from the ventricle. There was neither history nor evidence of syphilis or of tuberculosis. The nutrition was maintained. From the fetor of the breath, from the size, appearance, and origin of the tumor, from the age of the patient, a diagnosis of carcinoma was reached. Examination of a bit of tissue removed failed, however, to disclose the histologic structure of carcinoma, and the removal of the growth by the natural passages was decided upon. This was accomplished piecemeal in ten sittings. A small growth recurred; this was removed; the patient thereafter remained free. Histologically it was found that beneath a thick layer of epithelium was a connective-tissue stroma, sending papillary processes toward the surface; between these dipped epithelial processes; the lowest layer of epithelium consisted of fairly high cells, presenting here and there indications of division; toward the surface the cells were flatter, the uppermost layers being constituted of horny pavement epithelium. In the second case, in a man twenty-six years old, the symptoms had existed for eight years. The galvano-cautery had been employed with excellent results. The patient presented atrophic rhino-pharyngitis. The posterior wall of the larynx presented a hemispherical, grayish-white thickening, projecting for a distance of about a quarter of an inch into the larynx. The right vocal band, at its posterior third, was the seat of a pale-red, bean-shaped tumor, resembling the mass on the posterior wall of the larynx. Below the bands were several tumors of the same kind. A view of the left band was obscured by the mass on the posterior wall, but at the level of the ventricle a reddish prominence could be seen, on inspiration reaching almost to the middle line, and on phonation reaching still further to the right. The vocal band itself was thickened and posteriorly presented a depression into which the tumor of the right band projected. The subglottic mucous membrane was thickened. From the multiplicity of the growths, their circumscription, the absence of glandular involvement, the well-preserved nutrition, the age of the patient, together with the absence of evidence and history of syphilis and tuberculosis, a diagnosis of pachydermia verrucosa was made, and this was confirmed by subsequent microscopic examination. The administration of potassium iodide was followed by little change, so that by means of cutting-forceps the neoplastic growths were removed, a little at a time, until finally the patient was considered cured.

Incipient Posterior Spinal Sclerosis in a Case of Exophthalmic Goiter.—WIENER (*Inaugural Dissertation*, Berlin, 1891) has reported the case of a woman, twenty-two years old, who, for four months following childbirth, presented general nervous irritability, restlessness, palpitation of the heart, and itching of the skin. At the twelfth year of age, one foot was dragged for a period of time. Later there was anemia, which was relieved by treatment with iron. The patient was emaciated and anemic; the pulse was 130; the left ventricle was hypertrophied and dilated; the thyroid gland was enlarged; the eyes protruded; convergence was defective; the visual field was limited; the hands were hot and moist; sensibility to pain was diminished; the knee-jerks were wanting; attacks of vertigo occurred; memory was impaired; there was slight headache.—*Centralbl. f. klin. Medicin.*, No. 29, p. 611.

THERAPEUTIC NOTES.

Treatment of Uterine Hemorrhage.—ROUTH (*Practitioner*, July, 1892, p. 5) recommends that in case of profuse menorrhagia, and especially if metrorrhagia is also present, without obvious cause, the cavity of the uterus should be explored. The best means of exploration is rapid dilatation of the cervix with graduated bougies, under anesthesia. With rigid antisepsis there is practically no risk and rarely consecutive pyrexia, unless malignant disease or salpingitis be present. Even if tubal disease is present or suspected, exploratory dilatation of the cervix for hemorrhage of apparently intra-uterine origin is not necessarily contra-indicated, salpingitis often being secondary to and aggravated by intra-uterine disease. If fibroids of the uterus are evidently present, the immediate cause of the hemorrhage may be a removable one, such as a coëxisting polypus or fungous endometritis. The uterine cavity should, therefore, when practicable, be explored before removal of the appendages or hysterectomy is considered. In some cases dilatation alone suffices to relieve hemorrhage and pain. If exploratory dilatation were more commonly adopted prior to the employment of Apostoli's treatment, it would lead to a more exact knowledge of the applicability of the latter and place its use on a more scientific basis.

Recovery from Twenty Grains of Strychnine.—WALLACE and MCRAE (*British Medical Journal*, No. 1647, p. 179) have reported the case of a man, sixty-five years old, who was seen some seven or ten minutes after the ingestion of twenty grains of strychnine sulphate. Apomorphine, gr. $\frac{1}{8}$, was given hypodermatically; six tumblers of hot water, with three tablespoonfuls of mustard and three tablespoonfuls of salt, were administered by the mouth. Three ounces of tannic acid were likewise given, and the stomach was washed out by means of the stomach-pump. Finally a large dose of potassium bromide and thirty grains of chloral were given and strict quiet and absence of light and movement enjoined. There were twitchings and jerkings of the muscles of the limbs and tetanic spasms of the muscles of the lower jaw, with violent contractions of the esophagus. Emesis was prompt and energetic, and the man recovered.

Abortive Treatment of Erysipelas.—TALAMON (*Münchener medicin. Wochenschrift*, 1892, No. 28, p. 501) recommends the employment of a spray of sublimated ether (1 : 100) in the treatment of some cases of erysipelas. If the infiltration be not extensive, the application is to be continued until vesication occurs; if the involvement be extensive, the central portion is only to be moistened; as the periphery is reached, the application is to be more vigorous and should extend beyond the line of demarcation. But few applications are necessary. If the eyelids are involved, they should be covered with moist borated compresses.

SATURDAY, AUGUST 20, 1892.

THE TREATMENT OF PNEUMONIA.

SCARCELY any subject in the domain of practical medicine has been more discussed, and yet remains as unsettled, as the treatment of pneumonia. Changing views of pathology are responsible for much of the discrepancy of views upon the subject. In the olden days, as a matter of course, inflammation of the lung was treated by blood-letting and mercury. Antimony, too, had its vogue. With the reaction against venesection and the mercurials, and with the earlier advances in pathology, responsible for so much therapeutic nihilism, the expectant treatment was largely taught—and perhaps practised.

Drugging, however, was not entirely given up even when mercurials and bleeding were abandoned. Aconite, veratrum viride, and digitalis, widely differing in physiologic action, have in turn been strenuously urged for their influence upon the heart and circulation, in the attempt to overcome or compensate for the obstruction to the passage of blood through the hepatized lung.

With the acceptance of the germ-theory of disease and the discovery of the pneumonia-coccus apparently establishing the previously suspected infectiousness of pneumonia, the antiphlogistic methods of treatment, both old and new, have once more been discouraged; yet out of all the tumult a powerful voice is here and there still raised in strenuous advocacy of the lancet. We need but refer to DR. HIRAM CORSON, whose latest utterance took the shape of a paper recently read before the Philadelphia County Medical Society. As was well said by one of the speakers at the meeting in question, we must carefully discriminate among our patients. Whether or not there are actually different types of the disease, there certainly are many differences in the physical state and environment of those attacked by it, and a treatment that serves a good purpose in a given case, under certain conditions, may be worse than useless in another case, under different conditions.

Thus, the question as to the propriety of bleeding in pneumonia is one to which an invariable answer cannot be given. In a robust patient, at the very outset of the case, bleeding may cut short the progress of the disease; or again, when, during the progress of a case, a patient, robust or weak, is suffering from the mechanical consequences of obstruction to the free passage of blood through his pulmonary vessels, and the heart is over-distended and laboring ineffectually, depletion may have a beneficial effect by diminishing the amount, and to that extent favor a more equable distribution of blood in the body, and relieve the heart of a portion of its load. The loss of blood under these conditions cannot injure the patient, because, being stagnant and overloaded with toxic products, the blood has ceased to be either nutrient or energizing. The very removal from the circulation of a quantity of vitiated fluid may diminish the adverse influences against which the powers of recovery have to contend.

Under such circumstances, the administration of digitalis as a substitute for venesection would be futile. That which the therapeutist has to remedy is not a lack of power in the heart, but the conditions against which the heart is compelled to labor. Similarly, at this stage, the administration of the nitrites cannot replace venesection, but used earlier, intelligently, and vigorously, the use of the nitrites may prevent the occurrence of the conditions demanding venesection.

The time for the administration of aconite in the treatment of pneumonia is before consolidation has occurred; the indication is the same as for early venesection, and, used in this way, aconite is not unworthy of the name applied to it of the "therapeutic lancet." Unfortunately, however, cases are

not often seen at the stage at which aconite is most likely to be beneficial, and there is a time, which the practitioner of experience and judgment can recognize, when venesection will cut short the progress of the disease and aconite will not.

What are the indications for digitalis? These cannot be stated simply, for the problem is a complicated one. In certain patients and at certain stages of the varying progress of the case, a condition may be recognized in which the slowing of the rate of cardiac contraction, the heightening of blood-pressure, and the increased vigor of the systole, brought about by this drug, will insure a more equable distribution of the blood through the healthy portions of the lung and throughout the systemic circuit, thus practically permitting a cessation of function on the part of the diseased portion of the lung, but allowing the general physiologic processes of the rest of the body to go on with a minimum of disturbance. Again, it is only by experience and judgment, and familiarity with clinical indications gained by bedside study under the direction of an experienced preceptor, that this condition can be recognized.

Of veratrum viride we cannot speak with assurance, for we have no experience with it. It seems, however, to occupy a place midway between aconite and digitalis, but positive statements as to its value, and the conditions under which it should be used, must be left to those familiar with its action.

The ammonium salts play an important part in the treatment of pneumonia. The absence of chlorides from the urine, the well-known function of sodium chloride in preserving the fluidity of the blood-serum, the tendency to excessive fibrinous exudation, and to the formation of thrombi, characteristic of pneumonia, combine to give a therapeutic indication almost unmistakable. The fluidity of the blood must be maintained, and the most effective agents to this end are the ammonium salts. Three of these have special indications. Ammonium carbonate stimulates the heart as well as the respiration, and has a special value in what may be called the middle stages of pneumonia. Ammonium chloride, on account of the much larger doses in which it may be used, and possibly because it is a chlorine compound, is to be preferred in the earlier stages, when this special use of the carbonate is not necessary. Ammonium salicylate is of special utility as an antiseptic, and appears to exercise a peculiarly beneficial influence over the progress of those cases of pneumonia in which associated pleuritis is of notable extent.

In many cases the combination of ammonium carbonate, ammonium chloride, and, if the stomach will bear it, ammonium salicylate, has seemed to be of greater value than any one of the drugs alone.

The value of quinine in pneumonia is a question by no means settled. The weight of opinion is against its use, and yet there are many cases in which it seems to be beneficial. When a case is seen in its incipiency, the use of massive doses of quinine, so that forty or fifty grains are given in the course of twelve hours, is justifiable in the attempt to abort the disease. While the possibility of such abortion must always remain doubtful to those who insist that the diagnosis can only be made by symptoms that appear later in the pathologic course of the disease, there are not wanting those who claim to have observed cases of pneumonia aborted by such treatment.

External applications are sometimes of apparent benefit, though possibly more by equalizing the temperature and protecting the chest from drafts than from any direct or indirect influence upon the morbid process. Turpentine stupes and embrocations probably do more good by the collateral inhalation of turpentine vapor that attends their employment, than by the counter-irritation produced.

As a matter of course, the excretions are to be actively maintained.

Subcutaneous infusion (hypodermatoklysis) of saline solutions, as practised by F. P. HENRY, of Philadelphia, is unquestionably useful, probably by helping to maintain the fluidity of the blood in the same manner as the internal administration of ammonium salts, and by washing out noxious matters.

The inhalation of oxygen, while in no sense a curative measure, has its place in the management of a case of pneumonia, in the hope of keeping the patient alive until the morbid process has completed its course. The *rationale* seems to be that it supplies concentrated respiratory pabulum, thus compensating to some degree for the loss of aërating surface.

Under the stimulus of recent researches by BEHRING, the KLEMPERERS, KITASATO, and others into the natural processes of immunity and cure, a specific treatment of pneumonia has been proposed and practised, which offers a most encouraging prospect.

The lesions and untoward symptoms of the disease being attributed to a pneumotoxine resulting from the active invading microbe, natural recovery is held to depend upon the production of an antagonistic substance (anti-pneumotoxine) in the serum of the invaded animal. Thus Neisser (*Deutsche med. Wochenshr.*, No. 25, p. 593; The Medical News, July 23, 1892) has reported three cases of recovery of pneumonic patients treated by means of intra-venous injection of blood-serum obtained from convalescents two days after the crisis had occurred.

G. Klemperer (*Beilage zum Centralbl. für klin. Medicin*, 1892, No. 25, p. 41) reports twelve cases treated with injections of the serum of highly immunified guinea-pigs. In five of these the crisis took place soon after injection. In the remaining seven subsidence of temperature and slowing of pulse and respiration followed. Eight cases were treated with injections of a concentrated culture of pneumonia-cocci heated to 60° C. By this means the organism is supplied with the immunifying substances, from which it develops the curative factor. In all eight cases the temperature declined by lysis, the fall beginning from twelve to twenty-four hours after the injection.

In one case recently treated at the Philadelphia Hospital the experiment has seemed to be successful. The technique is simple, the only requisite being complete sterilization of vessels and tubes, and the complete defibrinization of the blood presumably containing the antitoxine.

DISPARAGEMENT OF OUR PROFESSIONAL ANCESTORS.

The following statement is found in an editorial in a recent issue of an American medical journal: "A hundred years or so ago our ranks were composed mainly of quacks and of impractical dreamers." Apparently this assertion is intended to apply to the profession not of this country only, but in general. Whatever the author's purpose, the remark will be considered by us as relating exclusively to American physicians. We question its truth for reasons that will now be presented.

Many of the practitioners of medicine in this country during the eighteenth century were educated in the best schools of the Old World before coming to the Colonies; many others who began their studies here completed them in famous institutions in Great Britain, or upon the Continent; and still others, born here, had their entire medical education abroad.

More than a hundred years ago, a successful medical school was in operation in Philadelphia, and one in New York, both established before the Revolution.

If the names upon the roll of medical teachers of "a hundred years or so ago" be compared with the names upon the roll of medical teachers of to-day, it will be found that there were quite as famous and able men then as now. Such a comparison will do no discredit to the men of the last century.

In the early days of medical teaching in this country the candidate for graduation was required to write a Latin thesis, and, from an examination[1] of some of these that we made a few years ago, it was evident that the authors had been carefully and capably instructed in Latin composition. These men had the mental discipline and the liberal culture that thorough study of the ancient classics gives. Here we beg leave to remark that we trust the day is distant when such studies shall be cast aside by those who are preparing to study medicine, sole attention being given to learning the physical sciences. However this may be, does it seem probable that students thus educated, "a hundred years or so ago," would be "quacks" and "impractical dreamers?" Would not the influence of such men rather have a strong tendency to elevate the profession? Is it probable, nay, even possible, that with such teachers and pupils there could be the condition described in the editorial we have quoted? To ask is to answer.

The times that immediately preceded the Declaration of Independence and which marked the Revolutionary struggle and the establishment of our system of government, were not favorable for "quacks and impractical dreamers" in any department of human effort.

If one recalls some of the illustrious names in the American medical profession in the eighteenth century—many of them those of great teachers, of eminent surgeons and practitioners of medicine, and observers and original contributors to professional

[1] One of the theses was by Dr. William Elmer, of Bridgeton, N. J., who became an eminent practitioner, and was also known as a patriot and a member of the United States Congress. It is an interesting fact that of Dr. Elmer's descendants, at least one in each generation up to the present time has been an honored member of the medical profession. Now, we believe, there are three.

knowledge—he will find that there were brave men before AGAMEMNON. The names of such men as the BARDS, BAYNHAM, BOYLSTON, BOND, CADWALLADER, CLAYTON, CRAIK, DORSEY, GRIFFITTS, PRESCOTT, REDMAN, ROMAYNE, SHIPPEN, TILTON, the WARRENS, HUGH WILLIAMSON, CASPAR WISTAR, above all in ability and fame, BENJAMIN RUSH, these, and more whose names might be given, can only be mentioned with reverent honor. Some of them were well known, not only in the profession, but also in council and in the field, assisting alike in the struggle for independence and in laying the foundations and erecting the superstructure of our national government. No man has occupied a larger place in American medical history than RUSH. CASPAR WISTAR was not only an accomplished anatomist, but an excellent teacher of anatomy and clinical instructor. It is doubtful if Philadelphia has now his equal, as certainly the entire country has not produced the peer of RUSH in medicine.

"A hundred years or so ago" there were several other great medical teachers, whose fame is part of the honor of the American profession. The motto of one of the oldest of English families is *Non generant aquilæ columbas;* and so such men as we have mentioned, whether teachers or practitioners, men who were neither "quacks" nor "impractical dreamers," did not produce a race of doctors materially differing from themselves.

Recognizing the important advances in medicine, especially in its scientific character, and remembering that humility is characteristic of true knowledge, we ought to beware alike of exalting our own attainments and of disparaging those of our medical ancestors. It is probable that the contrast between the profession as it now is, and as it will be a hundred years hence, will be greater than is that between the former and the profession as it was a hundred years ago.

SELECTION.

HIGHER MEDICAL EDUCATION.

WHY is it that admission to the profession of medicine in Massachusetts is at a disadvantage compared with admission to the profession of law? The very last thing the Law School or the Law Faculty would desire would be that their degree should admit to the bar. Other institutions have worked that out most thoroughly. Take, for instance, the school of law which is connected with Columbia College. It was demonstrated beyond a doubt that the fact that the law degree of Columbia admitted to the bar was a clear disadvantage to the school and to the profession. It is a clear disadvantage in medical education that the degree given by a faculty, a teaching faculty, should admit to the profession. The standard should always be outside, determined by another power.

Why is it that a full professor's salary in the Medical School of Harvard University—I mean for gentlemen who give all their time to the school, not the gentlemen who are in clinical or surgical chairs—why is it that the salary of a full professor giving his whole time in the Medical School is lower than in any other department of the university? Is this as it should be? That is the simple fact, it is lower; it is a good deal lower, than it is in the other departments of the university. Here is a point on which change should be promptly effected, that it is not fitting that the services of medical teachers should be so much lower than the services of other professional teachers in the same university. At best the scale of salaries for full professors in Harvard University is lower than in many other institutions, but in our Medical School we have the lowest full professor's salary. The gentlemen who serve in those chairs are not of less ability than those that serve us in law or in divinity or in the arts and sciences. They are not of less devotion.

All hangs on our English inheritances on this subject. In England the profession of medicine, the profession of surgery, does not now to-day stand on a level with the other learned professions. This is not the case on the Continent; it is conspicuously the case in England at this moment. They have the inheritance of the barber and the barber-surgeon still in their minds in England, and we have inherited two things from England, a lower standard of general education in the medical profession, the lower standard of requirement for admission to that profession or admission to the studies of the profession, and we have inherited this lower rate of compensation. I wish we could attach ourselves to the Continental schools of medicine rather than to the English in these regards. We have already far surpassed our English brethren in procuring for the medical and surgical practitioner the right standing in the community, in procuring for the medical and surgical practitioner the same standing which the lawyer or the preacher or the teacher holds; but we have something still to do with regard to the scale of instruction, previous training, required for admission to medical schools; and we have something still to do in the medical schools themselves in putting them on the right and equal basis of endowment which other professional schools, the schools of other professions, have already established for themselves.

The progress in medical education in our own university and in the other universities of the land made during the last twenty years, seems to me to be the most considerable progress that has been effected in any department of professional education within the same period. It is simply marvellous. When I look back on what was required of the medical school before the year 1870, not only in our own school but in many other schools, and compare it with what is required to-day, I see a progress which cannot be met in any other department of education, and I know that for that progress we are indebted largely to the prevailing sentiment in the medical profession. The Harvard Medical School would never have been able to carry out its changes of 1870–71—changes which reduced by nearly 40 per cent.

the number of students in the school, if it had not been for the support received through the expressed public opinion of medical men; and I believe that the change which is now before us, the change to the four-year course, will require the same kind of steady and enthusiastic support.—President Eliot, *Boston Medical and Surgical Reporter*.

REVIEWS.

Diseases of the Urinary Apparatus: Phlegmasic Affections. By John W. S. Gouley, M.D., Sen. Surgeon to the Bellevue Hospital. 8vo., pp. 353. New York: D. Appleton & Co., 1892.

This interesting volume consists of a republication and revision of the first part of a series of twelve lectures, which were delivered during the autumn of 1891, and subsequently published in the *New York Medical Journal*. They are offered by the author in this revised book form as a contribution to the pathology and treatment of a class of diseases the gravity and frequency of which render them worthy of the closest study.

Dr. Gouley is not an advocate of the operation of cystotomy, infrapubic or suprapubic, for the cure of obstinate cystitis with contraction of the muscular coat of the bladder. His method of treating such cases is by hydraulic dilatation of the bladder. The fluid used in irrigation is heated to a temperature of from 105° to 110° F., and injected into the viscus very slowly, one, two, or three ounces at a time, until a pint is used. This process is repeated once daily until eight, ten, or twelve ounces can be injected at once.

Dr. Gouley believes that a cystotomy may be of advantage as preparatory and adjuvant to hydraulic dilatation of the bladder, but without the latter the cystotomy will not effect a permanent cure.

The abortive treatment of urethritis is strongly condemned, as it should be. Dr. Gouley states that this supposed quick way of curing this complaint is as delusive as it is alluring, both to patients and physicians, for it seldom cuts short an attack, and, besides the great distress it causes, is often productive of grave effects upon the urethra and adjacent parts.

A brief outline of Dr. Gouley's views upon the subject of urethritis may prove of interest to our readers, as they differ somewhat from those of other authorities:

"1. There is no specific for urethritis, notwithstanding the popular belief in its existence.

"2. Urethritis cannot rationally be dealt with as a single phlegmasic entity, no matter what may be its cause.

"3. The treatment that is best suited to one type or stage of urethritis is often hurtful in another type or stage of the affection.

"4. Balsamics are contra-indicated during the first three stages of urethritis, and should not be administered until the fourth, or stage of decline, is fully established.

"5. Urethral injections are contra-indicated during the second and third stages, but may be used in the first stage and toward the close of the fourth stage.

"6. Injections of strong solution of nitrate of silver, or of strong solutions of any kind, are contra-indicated in all stages of urethritis.

"7. Urethritis is ordinarily too much and too vigorously treated. The more heroic and meddlesome the treatment, the greater the liability to accidents and complications, and the longer its duration.

"8. Confirmed acute contagious urethritis, under the most favorable circumstances and the most judicious treatment, rarely gets well in less than four weeks, except, of course, in the first attack in young and otherwise healthy men who are not over-treated. In the last-named cases it sometimes gets well in ten days or two weeks without medicinal treatment.

"9. Proper hygienic management is all-important in the treatment of urethritis; unless it is rigorously carried out, the medical and local treatments inevitably fail."

With this somewhat cursory review of an entertaining volume we would add our friendly criticism: the author has, in many instances, made use of a nomenclature that could have been improved by the employment of terms in more common usage. With this single criticism, the work may be heartily recommended.

Treatise on Gynecology, Medical and Surgical. By S. Pozzi, M.D., Professeur Agrégé à la Faculté de Médecine; Chirurgien de l'Hôpital Lourcine-Pascal, Paris; Honorary Fellow of the American Gynecological Society. Translated from the French Edition under the supervision of, and with additions, by Brooks H. Wells, M.D., Lecturer on Gynecology at the New York Polyclinic; Fellow of the New York Obstetrical Society, and the New York Academy of Medicine. Two volumes. New York: William Wood & Co., 1892.

The appearance of this book marks a new era in the development of gynecology. The author has devoted much elaborate study to the pathology of the conditions that lie at the basis of the various affections. Hitherto the subject of etiology has been treated on the most general principles, and all attention has been given to technique and those disputed questions of treatment that might have been more readily solved had the exact pathology been more clearly recognized. Assuming this principle (the importance of underlying pathologic conditions), the author has clearly defined the indications for treatment. In endometritis he has demonstrated the causal relation of microbic infection to the pathologic condition. He shows that in the genital canal there is a zone rich in microörganisms, which, after Winter, he calls the Dangerous Zone. Infection of the endometrium depends upon one of two processes: First, the penetration into the uterus and noxious influence upon the endometrium of the germs normally present in this zone, occurring from lack of resistance arising from general debility of the tissues, which reduces cellular vitality; second, upon the introduction of these germs into the cavity of the uterus by careless therapeutic procedures. This theory opens a wide field, in which gonorrheal and puerperal infection also figure.

As a result of these conclusions the author advocates: First, the utmost care in antiseptic precautions; second, active principles of treatment, shown especially in his recommendation of the curette.

The work is thoroughly abreast of the times in the subject of operative treatment, both as to indications and technique. In regard to the latter, the illustrations

in Volume I, in connection with methods of suture and hemostasis, and in Volume II, in connection with the treatment of fibrous tumors of abdominal evolution, and laceration of the perineum, should be especially consulted.

The care that has been devoted to classification should meet with the utmost appreciation from all who are interested in this subject, especially as shown in the division of salpingitis into inflammation without and that with cystic tumor. This classification sharply defines the indications for and against operative treatment.

The publishers deserve great credit for the arrangement and appearance of the volumes; the translator for his skill and faithfulness.

Appendicite et Périityphlite. Par Ch. Talamon, Médecin de l'Hôpital de Tenon. Small 8vo, pp. 248. Paris: Rueff et Cie., 1892.

This is the fourth of the series of little volumes by standard authors issued under the direction of Charcot and Debove. The subject of appendicitis is presented in an intelligent and conservative manner, and a careful reading will illuminate many obscure points appertaining to a pathologic condition, the real significance of which has only recently been recognized. While it is admitted that the cecum may be involved in various inflammatory processes, it is contended that these are never confined exclusively to that portion of the intestine, and that the symptoms occasioned form but a part, and a subordinate part, of the clinical picture. The classical train of symptoms hitherto known under the name of typhlitis is in all cases ascribed to an inflammation of the vermiform appendix. The work deals successively with the historical aspect of the subject, the lesions, the causes, the symptoms, the diagnosis, and the treatment. For therapeutic purposes cases are classified as medical and surgical. The former group includes cases in which the inflammation is confined to the walls of the appendix, or by extension involves but a circumscribed area of the adjacent peritoneum. If there be colicky pains, local and general sedatives are indicated, to be followed by an emollient enema. If evidences of inflammation are conspicuous, a dozen leeches should be applied at the seat of greatest pain, after which a gentle laxative, such as calomel or castor oil, may be administered. Subsequently, intestinal antisepsis is to be secured by irrigation and the administration of drugs by the mouth. If the peritoneum has become locally involved, an ointment of mercury and opium may find useful application. When the appendix has been perforated, with resulting general peritonitis, or peri-appendicular suppuration, surgical intervention becomes necessary. This should be undertaken as soon as it is recognized that the peritonitis is general. If the peritonitis is acute and circumscribed, operation should not be performed before the fifth day, while the best time for operation is between the eighth and twelfth days. In subacute cases incision is indicated as soon as the presence of pus is recognized.

Dr. J. H. McMillan, a graduate of the University of Pennsylvania in 1888, and a former resident physician in the Philadelphia Hospital, died of appendicitis at St. Louis, July 25, 1892.

CORRESPONDENCE.

NEW YORK.

The Board of Health—Sterilized Milk for the Poor—Skin-grafting—Tumors of the Bladder—St. Luke's Hospital.

About the only stir in medical circles of late has been due to the changes in the Board of Health. As some of your readers may already be aware, the "shaking up" in our police department was speedily followed by a number of important changes in the Health Board, which were of such a nature as to give color to the accusation that they were made chiefly for political reasons. Although it would be no surprise to many to learn that even this department, which is charged solely with looking after the health of our city, is tainted with politics, we have not heretofore been permitted to see so plainly the hand of the "boss," though his influence may have been none the less certainly felt. Here, as elsewhere, it is all-important to be possessed of a "pull," and one's tenure of office, as well as one's chances of promotion, bear a close relation to the strength of this hidden power. I have known one of the physicians connected with the Board to be deprived of his position without any charge of incompetency or neglect of duty, and in a few weeks to be reinstated through the influence which he was able to bring to bear upon the Board; yet in obedience to the demands of a more powerful but equally mysterious power, he was again displaced after a few weeks. The recent resignations, therefore, of such men as Drs. A. Jacobi and T. Mitchell Prudden may be looked upon as well-grounded protests against the methods pursued in the Board of Health. It is but natural that certain other medical gentlemen connected with the Board, who have been interviewed by the newspaper reporters, should not be anxious to make positive statements in regard to political interference, but it is noticeable that they do not deny its probable existence. It is bad enough that medical men in the employ of the city should, as a rule, receive so much smaller salaries than the legal gentlemen in the public service, but it is going altogether too far to allow these offices to be traded for votes. There is, indeed, good cause for apprehension when those who are entrusted with the important duty of attending to the sanitary condition of this large city are selected chiefly with a view to their qualifications as political leaders in their respective election districts. It is to be hoped that when this subject comes before the Academy of Medicine next fall, as it must do, it will receive the thoughtful and manly consideration which it deserves.

At this season of the year there is always more than usual interest taken in all matters pertaining to milk and to infant-feeding in general. Last summer, one or two of the larger dispensaries made an attempt to furnish sterilized milk to the poor, and, while there were many obstacles in the way of the success of this movement, the same institutions have felt sufficiently encouraged with their first experiment to warrant them in repeating it this season. On first thought, this would seem to be a very important and practical charity, and one quite easy to carry out, but experience has shown that the bright dreams of the theorist have not been fully realized. It is undoubtedly a great blessing to the poor in our crowded

down-town tenements to be able to obtain even pure unsterilized milk at a reasonable price, for a large experience among these people has taught the writer that it is well-nigh impossible in many of these districts to obtain good, reliable milk at any price, and hence, those children who are unfortunate enough to be deprived of their precious birthright—breast-milk—are almost universally fed on canned condensed milk.

The sterilized milk furnished by the dispensaries is dispensed in small bottles, one being intended for each feeding. Though the milk may be properly sterilized in the first instance, there are many sources of contamination difficult to avoid. Thus, if dispensed with the cotton plugs in the mouths of the bottles, it is more than probable that the people will tilt the bottles on their way home and so wet the cotton, and perhaps even spill the milk. It may be argued that this is carelessness, and is avoidable, but it must be remembered that the beneficiaries of this charity are densely ignorant, frequently both careless and lazy, and that even with the best intentions, it is very easy to tip the bottles and contaminate the milk when one has to carry a number of bottles of milk, perhaps one or two bottles of medicine, and a sick and fretful baby in the bargain. On the other hand, if the cotton plugs are removed and corks substituted for them just before the milk is dispensed, there is again a likelihood of infecting the milk. It is not difficult, then, to understand that it is easy in actual practice to neutralize all the good supposed to be derived from the sterilizing process.

Speaking of the quality of the milk, I am reminded of an interesting paper read before the Bellevue Hospital Alumni Association by Dr. John E. Allen, in which he described the methods of inspection and analysis in vogue in this city. The districts are frequently changed, as are also the inspectors, and a study of the reports of this department for the past few years shows that, as a result of the rigid inspection and enforcement of the law, there has been a constant and decided decrease in the number of arrests made necessary and in the quantity of milk destroyed each year, as compared with the total number of inspections. As the law requires the presence of a witness when a sample of milk is taken for analysis, or when a lot of milk is destroyed, the inspector is accompanied by a sanitary officer. When the milk is confiscated and destroyed, a sealed sample is given to the owner, and one sent to the chemist of the Board for examination. If any physician in the city has reason to suspect the quality of any milk-supply he has only to report his suspicion to the Board of Health, when a thorough inspection will be made, extending even back to the dairy, and a report sent to the physician.

It is a matter of everyday comment how rapidly modern surgical methods undergo modifications and improvements, and while the conservative surgeon looks askance on many of these changes, and fails to find as much real substantial progress as would at first appear, it cannot be denied that surgery is making most rapid strides, and that many important points in technique are overlooked by reason of its very rapid march. This observation would seem to apply with great force to the method of skin-grafting first brought forward by Thiersch, of Leipzig, in 1874, and which goes by his name. The method attracted no attention at the time of its first publication, and, in fact, it is only within the last half-dozen years that the method has been accepted as a useful surgical procedure. Only a very few years ago the Reverdin method with small skin-grafts was almost the only one in very general use, and, strangely enough, notwithstanding that it was tedious and disappointing to an exasperating degree, it held its place for fully a dozen years after Thiersch published his method. Now, a great change has come over the surgical world, and during the winter I received almost weekly invitations to be present at a "Thiersch skin-grafting."

Among the surgeons here who have given the method extended trial and study there is perhaps no more ardent advocate of it than Dr. Charles McBurney, and on this account it may perhaps be interesting to describe briefly his method of operating. The surface to be grafted is, of course, carefully cleaned, and all hemorrhage checked, and the surface from which the grafts are to be taken, usually the thigh, is rendered thoroughly aseptic. The grafts themselves consist of thin shavings of skin, from two to five inches in length and from one to one and a half inches in width, and they are removed with a sharp razor by a sort of sawing motion. Their removal is greatly facilitated, and larger and more uniform grafts secured, by holding the skin tense and flat by means of instruments made especially for this purpose. These usually consist of a broad flat piece of metal, with a handle and armed with teeth, which are pressed into the skin and held firmly by an assistant. If these instruments are not at hand the assistant may obtain a fair grip on the skin on either side of the field of operation by covering his hands with gloves made of Turkish towelling. As the grafts are removed they are placed in a ½ per cent. salt solution (a dram and a half to a quart). A useful point in the technique, and one sometimes overlooked, is the use of a piece of gutta-percha tissue as an aid in transferring the grafts from the salt solution to the area to be grafted. They may be quickly floated out flat upon a piece of this tissue, and from this slid off upon the wound. When the grafts are all in place, they are covered with strips of gutta-percha tissue, moistened with the salt solution, and over this are placed compresses wet with the same solution. The dressing is completed by covering the compresses with rubber tissue and a bandage. If the surface from which the grafts are removed be dressed in the same way there will be no discomfort, and healing will be complete in about a week; but if the surface be dressed with iodoform-gauze the granulations will creep into the meshes of the gauze, and the healing will be slower and more or less painful. Thiersch advocates changing the dressing over the grafts every four hours for the first few days, but Dr. McBurney has found this unnecessary, and has obtained equally good results by a change of dressing every two days. A dry dressing may usually be substituted after the first week. It will not do to bring the tender grafts in contact with strong antiseptic solutions, for these would destroy their vitality; *aseptic*, not antiseptic surgery is the keynote to success. If the surface to be grafted is covered with unhealthy granulations, these should be scraped away down to the original fatty layer, and then a bandage should be applied until the hemorrhage has entirely ceased. By this method not only are better results obtained than by the older

methods of skin-grafting, but the treatment rarely extends over as many weeks as it formerly did months. One of the most important advantages of the method is the latitude it affords the surgeon in operating upon malignant growths, for with the knowledge that he can quickly heal over a denuded area of almost any size, he no longer hesitates to cut very wide of the disease. It is not improbable that in the course of a few years, through the aid thus rendered by Thiersch's method of skin-grafting, the prognosis in carcinoma of the breast may be very favorably modified.

Another important aid has been rendered surgery by an improved method of examination in cases of suspected tumor of the bladder. In a suggestive communication on this subject, Dr. Frank Ferguson has explained the advantages of the new method, and has described the manner in which the examination is to be made. One has only to recall the numerous instances in which *large* tumors of the bladder are found at the time of operation, when their existence has scarcely been suspected, to comprehend the importance of this subject and to realize that hitherto our methods of diagnosis in these cases have not been what they should be. The method of examination advocated consists in collecting the sediment of the entire quantity of urine voided in the twenty-four hours by filtration through cheesecloth. Small fragments of tissue found in this sediment are then hardened in alcohol, embedded in celloidin, and numerous sections from these masses are then made and subjected to microscopic examination. The examinations should be made systematically and at short intervals. By this method Dr. Ferguson has been able to diagnosticate the existence of tumors of the bladder on several occasions, subsequent operations proving the correctness of his diagnoses. The usual method of collecting and examining the sediments from the urine is entirely inadequate in this class of cases.

The general tendency of our population to move to the upper sections of this city has led some of our hospitals to look for better accommodations in the same quarter. This is eminently proper, for it is certain that in this newer portion of the city they can secure more commodious and healthful surroundings. Among those to make a move in this direction is St. Luke's Hospital. Although the beautiful grounds surrounding the hospital in its present location on Fifth Avenue secure excellent air-space, the city in the immediate vicinity is closely built up, and more than all this, the building is not at all in accordance with our modern ideas of hospital-construction. A new hospital is to be built upon its recently-acquired property, at One-hundred-and-thirteenth Street and Morningside Park, alongside of the proposed Cathedral of St. John the Divine. The site is on high ground, and is a most excellent one from a sanitary point of view, and it is the intention of the hospital authorities to equip the hospital according to the most approved modern methods. It is reported that when the hospital removes to its new home it will be so far from the center of the city that several of the attending staff will find it so inconvenient that they will be compelled to resign. It is also rumored, but I trust that upon this point I am misinformed, that the hospital will open a dispensary. St. Luke's Hospital has always set its face against this sort of thing in the past, and has been so very careful not to infringe upon the rights and privileges of outside medical practitioners, that it has won for itself an enviable reputation in this direction, and it is to be hoped that it is not at this late day going to allow itself to be tainted with the modern dispensary idea. It has always had the interests of its patients at heart, yet it has heretofore been able to give them all needful attention without establishing an out-patient department or a dispensary, and we do not think any good reason has yet been presented for taking such a step.

CHICAGO

Quarantine Precautions—Cholera—Smallpox—Typhoid Fever—Regulation of Medical Practice.

THE Illinois State Board of Health met in this city, July 27th, at the Grand Pacific Hotel. There were present: Drs. W. A. Haskell, *President;* R. Ludlum, Chicago; A. L. Clark, Elgin; B. M. Griffith, Springfield; W. R. Mackenzie, Chester; D. H. Williams, Chicago, and Frank W. Reilly, Secretary of the Board.

The morning session was given up to executive business. An order was entered authorizing the secretary to issue a quarantine notice should Asiatic cholera, smallpox, or yellow fever appear in the United States or Canada.

The notice, as approved by the Board, declares contraband of quarantine any transportation company bringing into Illinois any person suffering from one of the three diseases named, or one who develops any of them within seventy-two hours after entering the State. This declaration having been made, the trains of any railway company or the vessels of any navigation company shall be stopped at the State line or before effecting a landing within the State, and held until inspected by a sanitary inspector of the Board and declared safe.

This action is based upon the inefficiency of quarantine regulations at the seacoast of both the United States and Canada. It is made the duty of all officers of the State and of officers of the peace to enforce the provisions of the order. The secretary was also ordered to submit for the examination of a bacteriologic expert any suspected case of Asiatic cholera in Illinois, in order that, on the one hand, groundless alarm may be avoided, and, on the other, that the presence of the disease may be positively determined at the earliest moment.

Smallpox was reported to have made its appearance within the last few months in Austria, Bavaria, Belgium, Brussels, Ceylon, Chile, China, Cuba, Egypt, England, France, India, Italy, the Netherlands, Poland, Russia, Spain, Sweden, and Switzerland. As a results of its prevalence in England, it has been introduced repeatedly into this country within the past three months. Outbreaks have been reported in New York, New Hampshire, Rhode Island, Pennsylvania, Ohio, Michigan, Wisconsin, Iowa, Nebraska, New Mexico, California, British Columbia, and the Dominion of Canada. Three cases have been imported into Chicago. As a result, the Board is insisting upon vaccination throughout the State. The Surgeon of the Third Regiment of the Illinois National Guard, now encamped at Springfield, has applied for material for the vaccination of his command, and Dr. Dewey, of the Kankakee Insane Asylum, has been furnished 1800 points for use in that institution.

Many of the railroad companies and large manufacturing companies have also undertaken to secure the vaccination of their employés.

The secretary reported progress in the investigation of the Chicago typhoid fever question, and presented maps giving the location of every death by typhoid fever during the years 1891 and 1892 respectively. These maps have been prepared at the secretary's request in the clerical department of the Chicago sanitary district. This study and analysis, together with the study of the sanitary conditions of the various localities, the character of the soil, of the filling-in material, of the sewerage and drainage, of the habitations and of the population, will form the groundwork for the report on which the secretary is now engaged. That there is more or less causal relation between typhoid fever and the character of the water-supply in this city would seem to be borne out by the partial study already made of these maps, but that there are other factors included in the problem is also clear.

A report was made on medical schools by the committee—Drs. Clark, Griffith, and Ludlam. Upon it were based several orders. One demands a supplementary examination in writing before the Board of all graduates from a medical school in existence less than five years.

The rules recommended in the report provide: 1. That any established and legally chartered medical institution shall be held to be in good standing when its requirements for a medical education are those prevailing in a majority of the reputable medical colleges of the United States and Canada; 2. That not less than five years' actual existence and compliance with the first regulation shall be necessary to establish its reputability; 3. That graduates of schools other than those first described may obtain State certificates by passing examination in ten specified subjects before the Board, for which no fee shall be charged; and, 4. That any medical institution which is not recognized by the American Medical Association, the American Institute of Homeopathy, the National Eclectic Medical Association, or by the American Association of Physio-Medical Physicians and Surgeons, as the case may be, shall be declared and held to be not in good standing for the purposes of the Illinois Medical Practice Act.

It was also ordered that the diplomas of the institution known variously as the "German College of Medicine and Obstetrics," as the "German-American Homeopathic Medical College," and as the "German Medical College," 512 Noble Street, Chicago, Illinois, be not recognized by the Illinois State Board of Health, and that State certificate No. 8219, issued April 21, 1888, by the State Board of Health, be revoked and declared null and void, proof having been submitted that the present holder of said State certificate, one Philip H. Simons, *alias* Philip Simon, *alias* Charles Rohning, of Brussels, Calhoun County, in the State of Illinois, is guilty of unprofessional and dishonorable conduct, and any act of practice of medicine or surgery in this State on the part of the said Philip H. Simons, *alias* Philip Simon, *alias* Philip Rohning, is illegal under section 12 of said Act.

Before the adjournment Drs. W. A. Haskell, B. M. Griffith, and W. R. Mackenzie were elected delegates to attend the meeting of the American Public Health Association in the City of Mexico, November 7, 1892.

CODE OR NO CODE?

NO CODE.

To the Editor of THE MEDICAL NEWS,

SIR: You say opportunely and pertinently, "We are confronted with a condition and not a theory."

Permit me to state the condition:

I. The presence throughout our country of a medical profession many times more numerous than required for the good of the country.

II. The presence and active functioning of an absurd and scandalous number of private concerns—medical schools—whose chief object in life is to add largely to this already overfilled profession, regardless of the qualifications, fitness or competency of the men and women so added.

III. The natural and resulting condition that in the public estimation the average doctor is no better than the homeopathist, the eclectic, the clairvoyant, the faith-curer, and not nearly so good as the patent-medicine man, or the bichloride-of-gold healer.

This, at any rate, was the condition prior to 1878. Upon this scene enters the Judicial Council of the American Medical Association, composed of the men chiefly responsible for the condition you and we all recognize, with a recommendation destined to live as the greatest piece of economic charlatanism in history—the code of ethics of the American Medical Association. Whoever subscribes to this code becomes thereby an honorable member of the American medical profession, howbeit, he himself may be unable to read, write or cipher.

In 1878 the people, recognizing the "condition" and the quackish practice of the American Medical Association, led by the great Commonwealth of Illinois, began a very different treatment by adopting State license as a the only means of securing the services of a competent medical profession. Alabama, Florida, Minnesota, Mississippi, Missouri, Montana, New Jersey, New York, North Carolina, North Dakota, Oregon, South Carolina, Virginia, Washington, and West Virginia, for the sake of their people, whose lives and health they desire to protect, have placed similar laws upon their statute books, and in these States the code has ceased to have a *raison d'être*.

The people have made the diagnosis, the people have taken the condition in hand for treatment; meanwhile, the American Medical Association has only to waste time in the matter of code revision as it did in the matter of raising the standard of medical education, and in the near future State license will become the rule in every part of the American Republic. Then revision or no revision will be matters of equal indifference. A really learned and honorable medical profession has no need of *fiat* respectability.

HENRY REED HOPKINS, M.D.

BUFFALO, N. Y.

THE NEED OF A CODE.

To the Editor of THE MEDICAL NEWS,

SIR: Responding to the call of your editorial of July 16th, asking for "short and pithy" communications on "The Proposed Revision of the Code," I would offer a few suggestions on the primary or fundamental questions discussed in your editorial, "The Need of a Code."

For this purpose the profession may be divided into three distinct classes: 1st. Those of "honorable repute and blameless life"—your "Gideon's band," a select, very small, highly intelligent, and cultivated class. 2d. A class quite the opposite in morals, possessing intelligence and culture of a high order, yet baseless, unscrupulous rascals—numerically a very much larger class. 3d. An intermediate class, partaking of the elements of moral character of the other two variously mingled, and in intelligence and education rating below the average of each.

Some, as you have suggested, will maintain that a code is inapplicable to the first two—as being unnecessary in the one instance, and as powerless for good in the other. This I deny. On the part of the first it is a public and continual protest and maintenance of right and honorable conduct, as against the conduct of the second class before the enlightened world, thus helping to give each its mark of distinction. Particularly is this difference between the two classes capable of being made emphatic and pronounced in intelligent communities, where the code has been judiciously circulated among the laity.

If inapplicable, however, to the first two classes for a direct and personal effect upon the conduct of either, I hardly think it can be regarded as such for the third class, numerically the largest of all. The code, as maintained in practice by the first class and published to the world, circulating among all classes of reading and thinking laymen, as well as of physicians, has an *educational and reformatory* effect upon this element in the profession. By this class the code is oftener slighted or violated through sheer ignorance or misapprehension than otherwise. And herein, indeed, lies the fundamental truth in regard to the use and application of all law—the prevention of crime or wrong conduct through the education and reformation of character. And in this connection, and to conclude, would a recitation or two on the code, with a few instructive illustrative lectures before graduation, be out of place in the curriculum of the medical schools? Yours, etc., GEORGE COWAN.

DANVILLE, KY.

NEWS ITEMS.

The American Dermatological Association will hold its sixteenth annual meeting at New London, Conn., September 13, 14 and 15, 1892.

The arranged program will include the following:

President's Address.

"Iodine and Carbolic Acid in the Treatment of Skin Diseases," by Dr. C. W. Cutler.

"Additional Note on the Treatment of Erysipelas, Based Upon a Second Series of Fifty Cases," by Dr. C. W. Allen.

"A Suggestion for Operative Procedure on Erectile Nevi Over Fontanels," etc., by Dr. S. Sherwell.

"How Should Dermatology be Taught?" by Dr. G. H. Fox.

"A Somewhat Unusual Case of Lupus Ulceration of the Nose," by Dr. H. W. Stelwagon.

"Lupus Vulgaris following Exposure to Tuberculous Sputa," by Dr. W. T. Corlett.

"Notes on the Treatment of Lupus Erythematosus," by Dr. J. Zeisler.

Discussion on Alopecia Areata:

1. Are there two forms of alopecia areata; one parasitic and one neuropathic?

2. Is there sufficient evidence to prove the contagious nature of the disease?

3. Does arsenic or any other internal remedy influence the course of the disease?

4. What is the comparative value of carbolic acid, and of other topical remedies?

5. Will epilation of the margin of the patch prevent its spread?

6. What circumstances influence the prognosis of the disease?

"Alopecia Prematura; Its Most Frequent Cause," by Dr. G. T. Elliot.

"Cases of Favus Contagion from the Lower Animals," by Dr. S. Sherwell.

"Some Observations on the Growth of Achorion Schœnleinii in America," by Dr. L. Heitzmann.

"Morphea Atrophica," by Dr. R. W. Taylor.

"Psorospermosis," by Dr. M. B. Hartzell.

"Report of a Case of Adenoma Sebaceum, with Microscopic Drawings," by Dr. J. A. Fordyce.

"Concomitance and Sequence in Skin Eruptions, and the Influence of One Dermatosis Upon Another," by Dr. C. W. Allen.

"The Cicatrices of Syphilis," by Dr. J. N. Hyde.

"An Unusual Case of Syphilis," by Dr. R. B. Morison.

"An Exaggerated Case of Impetigo Contagiosa," by Dr. G. T. Elliot.

"Notes On a Recent Visit to the Leper Hospital at Havana; Leprosy in Charleston, S. C.," etc., by Dr. W. T. Corlett.

"Notes on the Use of Thilanin," by Dr. G. H. Fox.

Third Congress of Tuberculosis.—The Third Congress of Tuberculosis will be held at Paris in the latter part of July, 1893. The following propositions will be discussed: The role played by contagion and heredity, respectively, in the propagation of tuberculosis. Infectious diseases as provocative causes of tuberculosis; the part played by certain of them in the localization of tuberculosis; for instance, gonorrhea in the development of tuberculosis of the testicle, influenza in the development or aggravation of pulmonary tuberculosis. The lulls of tuberculosis; their duration; the means of recognizing their cessation in advance; the causes of recurrence. The various means of diagnosis of bovine tuberculosis, in particular the determination if the inoculation of tuberculin is a certain means of diagnosis of tuberculosis in cattle. The dangers that may arise from the interment of the bodies of tuberculous persons; the wisdom of the substitution of cremation for interment; the necessity for destroying the tubercle-bacilli in cadavers. New modes of treatment, prophylactic and curative, based upon etiology. The utility of the generalization of inspection of meat. A prize of 3000 francs ($750) will be awarded the best essay upon "The Means of Diagnosis of Latent Tuberculosis, Before its Appearance or After its Cure."

CORRECTION.

On the tenth line from the bottom of the second column of page 131 of THE MEDICAL NEWS of July 30th, the figures 108 should have been 103.

THE SURGICAL CARE OF WORKMEN.[1]

BY ROBERT W. JOHNSON, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE BALTIMORE MEDICAL COLLEGE.

AT first sight there would seem to be no difference between the surgical treatment of a workman and that of any other man, but I hope to show that as a class workmen have peculiarities and surroundings that merit consideration apart from the universal rules that apply in all surgical cases.

Let us at the outset define what we mean by a workingman. He is the laborer, the man who toils with his hand rather than with his head, and uses his muscles rather than his brain. He follows rather than gives directions, and taking the analogy from the Old Testament, is a "hewer of wood and drawer of water." As to his surroundings nothing definite can be said. He may live in a fairly comfortable two-story house, or on a floor in a tenement, or, if a single man, in a shanty near his work. He is paid by the hour or day, and he earns from seventy-five cents to three dollars *per diem*. He forms the vast majority of the body politic, shapes legislation by his aggregate vote, in the main is endowed with some education, his share of common sense, and more than his share of temptation and vice. From the nature of his employment he is liable to injury more than any other class. He is exposed to vicissitudes of weather, the debilitating effects of heat, and cold, and wet, as well as the more salubrious surroundings of out-door life, or the unhealthy prison atmosphere of dust-laden manufactories.

Except as these conditions influence him as a surgical patient, we must must not take time to consider them, and though his face is familiar to every hospital physician, covered perhaps with the grime of the furnace, or with the twilight glow of hectic, so soon to sink into the night, we must limit our view of him to the surgical aspect. He is ever with us, not so much as the victim of surgical disease as of accident. He is no more liable to tumors than his fellow-man at the desk or bar, not so liable to stone as his superior on the bench; but dealing with machinery of immense power, or endeavoring to overcome the forces of Nature, whether of gravity in the quarry or of cohesion in the mine, or storm at sea, he is torn asunder, and presents all the varieties of shock and laceration, contusion, and often sepsis, that are possible. Not only are these enemies at work, but from poor surroundings, miserable food, bad inheritance, he often brings with him the trail of the serpent left by the sirens of the bawdy-house and bar-room. Perhaps he is a moral family man; here virtue does not bring its own reward. He is depressed with the outlook for his family in case of death, or their want during his forced absence from work. I have seen cases far more anxious on this score than from any danger to which they were personally exposed.

Does the laborer have any inherent advantages to offset this catalogue of detriment? A few, but hardly compensatory. As a rule, the laborer, especially employed out of doors, has a stronger constitution, is less nervous, not so high-strung as the mind-worker. He bears pain with Spartan fortitude, his imagination is not so vivid, and he anticipates less acutely; he is often stoical, rallies easier, is not effeminate, but essentially manly. He has what is commonly called "grit." To him, moreover, the chances are that hospital fare is a treat he does not have at home. His stomach is stronger, and he retains his nourishment better than the members of the pampered class. He feels the transition from activity to bed, but soon gets acclimated. Here let me insist on the immense advantage hospital treatment presents to the laborer over his home care-taking. Besides the greater creature-comforts, such as bed, appliances, regular meals, and systematic treatment, he is relieved of the continuous presence of anxious and solicitous faces, the gossip and the universally bad prognosis of neighbors, who never saw a case like his recover, the continuous trial of new specifics suggested, from a poultice of cowdung to inunctions of holy water. In the hospital he has the systematic care of the trained nurse, cool, used to such conditions, the watchful observation of the house-surgeon, noting real changes, and notifying the surgeon-in-charge, if necessary. In a word, the laborer, though he often refuses the aid, throws away at least 25 per cent. of his chances of recovery by going to the loving but inexperienced care of home rather than the hospital, a place where those concerned make it their business to get their cases well.

[1] Read before the Maryland Medical and Chirurgical Faculty, April 26, 1892.

Let us look incidentally at the practical question, "Who is to support the laborer during the time that he cannot earn his daily bread?" It would be impossible to enter into the politico-economic question now seeking solution on a large scale throughout the world, especially in Germany and in England, as to the pension and insurance of the workingman. That there is no definite answer yet agreed on as the result of national experiment goes to show that the ultimatum is not yet reached. Suffice it to say that the modes generally in vogue are:

1. By means of public charity. The support by State or individual munificence of beds in large hospitals. While this must ever remain, to a certain extent, it presents disadvantages (*a*) in that the laborer gets no help when at home; (*b*) he feels that he is a charity case, and it has a tendency to pauperize him and diminish his self-respect; (*c*) he is under these circumstances, justly or unjustly, the object of perfunctory care, the subject of more or less experiment in the trial of new drugs or appliances or methods, for in this way remuneration for the outlay in taking care of him is justly or unjustly considered; (*d*) unfair advantage is taken by persons able to pay.

2. At the man's personal expense. This, in a vast majority of cases, is impracticable. His family uses up all he has when he is at work. It is not possible to meet the additional charge of from three to five dollars per week when he is out of employment, and, if treated at home, some essential drug or nourishment may be curtailed by reason of the rapid disappearance of the fund laid up for a rainy day, or what soon becomes a rainy season.

3. The employer looks after the men injured, pays their hospital expenses, and allows them part pay during their illness, when that illness is contracted in the line of duty, or the employer feels that his firm is in some way responsible for the attack. This method has some advantages, especially to the capitalist, in that a man who receives kind treatment at the employer's hands is less inclined to litigation than when he is thrown on charity or his own resource, but it partakes of the charity element in that the laborer pays nothing for his own maintenance. Again, his relief is spasmodic; he is not sure that if taken ill, unless injured, he will obtain any help, and we all know how much more frequent illness comes than injury.

4. The last method I will mention is that of a mutual insurance concern among employés. This is in vogue on some of our great railroad systems, and has much to recommend it. Men pay while they are well a certain proportion of their earnings into a common treasury—say a dollar a month, an amount hardly appreciable at the time, a mere *pourboire*, which is, perhaps, rescued from that untimely fate, and they obtain a certain amount per week when ill or injured; and though they may have been in the association only a few days they can feel that they have complied with its requirements, and, if laid off by accident, are really entitled to the benefits, or rather the rewards of their foresight. In my mind this method has the one objection that it does not associate the employer with it.

My opinion is that the best way to look after the workmen in large companies is by a partnership between labor and capital in taking care of the sick. Let each member of that partnership, the firm and the laborers' benefit association or insurance, pay half the expense of taking care of the ill and injured in employment. This begets good feeling without so much expense on the part of the employer and insures the workman against illness as well as injury, without the idea of pauperism for the workman. I think in this way litigation may be curtailed as much, if not more, than by the method in which the employer pays all; for the workman who brings suit against the insurance association feels that he is not only suing his employer but his fellow-workman as well. My experience with men who have thus subscribed for their own maintenance leads me to believe that it is not irksome—and that, too, in a class the least provident and the least amiable, *i. e.* the common sailor of the merchant marine and oyster boats; but I cannot go further into this interesting question.

Supposing the sinews of care-taking have been provided and we have our patient in hospital, what are the surgeon's duties then? They naturally fall under two heads—his duty to the laborer-patient and his duty to the company that employs him. They are so closely associated that I shall not attempt to differentiate them.

I think somehow the operating-table is a more democratic platform than the post-mortem table. Nowhere is a man "a man for a' that" more than when you are about to cut him, whether he be pauper or millionaire. His robes of office or his overhauls have been stripped off, and he lies before you clothed in humanity, appealing to your sense of human kindness as well as your professional skill. He needs your kindness, your cheer, your sympathy. Treat him as a intelligent being. State facts to him, and let him decide. It may take a little more persuasion or a little clearer advice. It may require a little more patience than with his more cultivated brother of the Stock Exchange, but let *him* decide, and act on his decision after you have explained the circumstances.

Avoid force, or intimidation, or coercion. The chances are that, since so much of surgery is mechanical and common-sense, you will find your

Hodge more amenable than your clerk. On your own account never operate without his permission, except in emergency or his inability to give it. Do only recognized operations, with well-tried methods, that would acquit you before a jury of any desire to experiment; for this workman, with all his good qualities, is susceptible of a desire to obtain damages from somewhere, when he recovers and has the slightest pretext for asking them. For the same reason, let your prognosis be guarded. Do not be too enthusiastic, and while I consider it a species of highway robbery to steal his or his family's sleep by causing undue anxiety, do not be too roseate about results.

Shock is one of your greatest adversaries. The force attendant on injuries to workingmen makes this a prominent feature of their lesions. I have found that hypodermatic injections of morphine and atropine, strychnine, and heat, hot coffee internally, or hot milk punch, very effective in tiding over this rock. Wounds and compound fractures I have disturbed as little as possible. Rest is to be secured by splints, and asepsis by the application, over blood-clot formation, of iodoform and mild bichloride gauze, a stock of which, together with other emergency necessities, cots, etc., I have distributed in various available locations about the works.

One cannot be too conservative about amputations. It is marvellous how much injury a hand or foot may receive, and yet come out under aseptic treatment a useful member. I have found that patients, without exception, prefer to preserve a heel or a small portion of the foot to amputation higher up the leg, and my experience justifies them in their selection, as they are able to stump around and have artificial feet made that are as comfortable and convenient as a false leg would be. It may take longer to heal than the higher amputation, and require more nursing; but I am not one of those who would care to fly so in the face of the patient's prejudice unless I saw commensurate advantages undisputed.

There is, I know, some difference of opinion in regard to the advisability of the mediotarsal or Chopart's amputation.

Jacobson[1] says: "The value of the operation has been a good deal disputed."

Treves[2] says: "The value of the operation is open to serious question."

Stephen Smith,[3] quoting Hudson, says: "The tarso-metatarsal and mediotarsal amputation will not hereafter be performed when there exists intelligent and humane regard for improved surgery and the greatest benefit of the sufferer."

[1] Surgical Operations, p. 958.
[2] Manual of Operative Surgery, p. 433, vol. i.
[3] Operative Surgery, p. 856.

On the other hand, it has the valuable commendation of such men as Agnew,[1] who says: "I do not think the danger of the cicatrix drawing down is an insuperable evil."

Bryant[2] says: "Chopart's amputation is an excellent and valuable operation, and should be always be performed in preference to any higher measure."

Erichsen[3] says: "The result of this operation is extremely favorable, the patient, by the aid of a properly constructed boot, being able to walk, and even to dance."

Moullin[4] says: "The stump left by the operation is, in many cases, exceedingly good."

"Mr. Hancock has collected 152 cases of Chopart's amputation, of which 120 resulted in recovery, with serviceable stumps, 2 in reamputation, 11 in death, while in 15 the result as regards utility of limb was uncertain, and in 4, though life was preserved, the stumps were not satisfactory."[5]

Coming to conservative operations on the hand, there are two that demand a passing word in this connection and about which there is more or less controversy among surgeons.

The first is the question of amputation at the joint between the first and second phalanges of the little, ring, and middle fingers. The opposition to this amputation arises from the fact that there will be no flexor attachment to the remaining phalanx, which will stand out as an obstacle when the other fingers are flexed.

Thompson,[6] in a valuable contribution on the "Surgery of the Hand," says:

"In amputation, to remove as limited a portion of the finger as possible is, in the main, proper, but exceptions should be made to this rule in amputating the middle and ring fingers, especially among the laboring class. Experience satisfies me that among that class it leaves the most useful hand to remove the middle and ring fingers at the metacarpo-phalangeal articulation, as a stump from amputation in the continuity or at the phalangeal joint, the flexor and extensor muscles having been severed, renders the hand comparatively useless, and is, therefore, much in the way of the laborer in performing his work. I am more convinced that it gives a better result to amputate those fingers at the knuckle-joint."

In the discussion provoked by this paper Dr. L. McLane Tiffany stated that:

"It is true that if amputation is made through the first phalangeal joint a useless stump is left; but there is no earthly necessity, as far as I can see, why the tendons which naturally pass over the joints should not be made to have an attachment after

[6] Transact. Amer. Surg. Assoc., vol. ii, p. 188, *et seq.*

amputation at the joint. In other words, when the flaps are made, the stitches which unite the skin can also be passed through the tendons and their sheaths. I have done this for a number of years, and I have never failed, as far as I can remember, to secure quite as good movements of the second and third fingers as if Nature had originally made an attachment there for these tendons."[1]

Dr. Maclean stated that he has hardly ever seen a patient who had such movement of a stump of this form. Agnew, Erichsen, and Jacobson disparage the operation. Moullin advises it under certain conditions.

My own practice in this regard is to consult the man's wishes, at the same time telling him that it is possible to correct the failure of the stitched tendons, flexing the phalanx by a subsequent operation, with little or no risk. As a rule, the decision is in favor of the phalanx, and, so far, I have had no complaints.

The last specific operation to which I shall refer is one to which the question of utility vs. esthetics is more marked—namely amputation at the metacarpo-phalangeal, or knuckle-joint. Shall the head of the metacarpal bone be allowed to remain, or shall it be excised in order to conduce to the symmetry of the hand. Authorities again differ.

"In a laboring man it is wise not to remove the head of the metacarpal bone."[2]

"When, however, the patient's employment is one in which great strength and breadth of hand are required, and when appearance is of little consequence, the head of the bone may advantageously remain."[3]

"The hand may be rendered more symmetrical by the removal of the head of the metacarpal bone, but the gain of symmetry is more than counterbalanced by the loss of firmness and strength."[4]

"In all these disarticulations the head of the metacarpal bone should be spared whenever possible."[5]

"When strength has to be considered rather than appearance, the head of the metacarpal bone should be left."[6]

In these cases in laboring men I invariably save the head of the metacarpal bone if possible.

Asepsis is so difficult to maintain or to secure in hands and feet and scalp begrimed with furnace smut and driven in by contusion and laceration, that we have in the blood-clot treatment of Schede a great advance in accident-surgery when organization can take place in the deeper parts before pus-organisms have gotten a foothold and resistance is made and the field occupied by Nature's methods in advance, suppuration being discounted as it were.

To reduce the armamentarium of the operator, when called to see workmen at their homes and when there are not the same facilities for aseptic work as in the hospital, I have devised a kettle containing trays, which, fitted with the respective instruments and dressings, may be boiled while the patient is preparing. I boil everything, using silk ligatures and sutures in proper lengths wound on glass. I have substituted for the rubber tissues (which balked me in this respect) the thin scales of transparent mica to protect the clot, and which stand any amount of boiling or acids or bichloride. They, as well as the other essentials, a wash-boiler, with meat-dishes or plates to hold the trays, may be obtained in any house where there is a stove. The dressings after boiling should be impregnated with a mild bichloride solution, for, while the boiling renders them aseptic, it does not make them antiseptic. I feel competent in an emergency now to venture, with these simple appliances, *i. e.*, a pocket-case, a few tablets of bichloride, into a laborer's house and find those articles used in his domestic life which will give me material assistance in antiseptic work, and render suppuration more and more inexcusable, even in back country districts or with druggists out of sight. I need not dwell on the great value of pressure in eliminating dead spaces by elastic cushions of gauze, supplemented by lino, which when dry forms a splint.

In the interest of the company have the testimony of eye-witnesses taken at the time of the accident, so that you can present that to a jury if necessary, and not be dependent on garbled, forgetful, or partial memories should the case come in court. Inform the man's family gently of his condition from time to time, see him every day and impress him with your sincerity and attention. Avoid the publication of accidents in the daily newspapers as far as you can, as there is a "shyster" in law as there is a "quack" in medicine, who is on the lookout for damage suits for a contingent fee, and though I have known the name in print to act as a temporary balm to the friends of the injured man, and perhaps to the sufferer himself, I think it best for the interest of all concerned that matters move on without the interference of the public. So, do not court the reporter in the hope of seeing yourself advertised. You may often be asked by the patient whether or not, if you were in his place, you would sue for damages. Decline to be anything but the surgeon in charge of the case; do not oppose him, or he will think you in league with the company. Simply tell him that you are his physician and not his lawyer, and he must decide. Should your patient obstinately refuse to follow your surgical

[1] Loc. cit., p. 226.
[2] Bryant's Surgery, p. 1013.
[3] Erichsen's Surgery, vol. i, p. 90.
[4] Ashhurst's Surgery, p. 118.
[5] Treves's Man. of Oper. Surg., vol. i, p. 332.
[6] Jacobson's Surgical Operations, p. 23.

advice, it is well, as protection to yourself and your employer, to obtain a *written* acknowledgment of your proposition and his declination, or, if he declines to give you that, get the corroborative testimony in writing of several fellow-patients in regard to your offer and his obstinate refusal. There is no comfort in his verbally declaring that he will take the responsibility of his act; see that you are protected in black and white.

All these precautions and cares, however, will sometimes be of no avail, unless the company you represent second your endeavors, not with parsimonious, penny-wise policy but in the same spirit and liberally. This they can do if they contribute to the care of the injured by meeting your suggestions cheerfully, going to the necessary expense in necessities, and, more than that, wisely allow the injured man some privileges and actual money, say half-pay, while sick, in addition to his hospital cost, or if the company and men contribute equally, doing it cheerfully and punctually. Then, in the after-treatment, they can do a great deal toward smoothing matters over—an easy position for awhile to an injured man, where he can earn his living without too much hard work, gradually getting him back as he improves into his old or a better position. Men appreciate the opportunity to earn a living, in my experience, far more than they do a money benefit. A little attention on the part of the heads of the firm, a casual inquiry of a man how he is doing, all these little thousand and one ways of showing that the employer does not look on his laborer as a machine, to be cast into the gutter when broken or even useless, bring about the *entente cordiale* so requisite in the harmonious working of large bodies of laboring men.

Should, in spite of the methods mentioned, a man who has been hurt insist on damages, except as far as your prognosis is asked, you have nothing to do. With the law you are not an expert; to your employer you can only say what is your unbiased opinion as to the extent of damage done. You have nothing to do with the placing of responsibility on either party, and your testimony should be as impartial as if you had been called as an expert in a hypothetical case. You have no right to take sides in your testimony; though, as an employé of the company, you can suggest questions to the attorney for the possible confutation of the plaintiff's medical testimony. In the last connection, *i. e.*, lawsuits, I am glad to say, I have but little experience.

During the last five years I have been connected as surgeon with some of the largest manufacturing and labor-employing concerns in this State. In one alone, the medical department has treated over five thousand cases of accident and illness, ranging from fracture of the vertebræ, with long-suffering life in the hospital, to contusions of the little finger. In that list may be found death, loss of sight, disfigurement, loss of limbs, double fractures, in fact, everything nearly that can constitute an injury or ailment, and, yet on this system described, with careful and kindly work in the same line by my assistants (many cases of small injury I never see), together with the hearty coöperation and liberal seconding I always cheerfully get from the heads of the firm, we have treated, as I said, five thousand and more cases, and there is yet the first suit for damages to be tried against this firm. I do not claim it as my work, nor do I say that it is altogether that of others. We have done it conjointly, and I feel a certain amount of pride in pointing out the modicum I had in bringing it about.

THE INFLUENCE OF THE NERVOUS SYSTEM ON CERTAIN DISTURBANCES OF THE SKIN.[1]

By A. RAVOGLI, M.D.,
of Cincinnati, O.

In the skin, more than in any other organ of the human body, the alterations of the nervous system presiding over the nutrition of the tissues are readily apparent, because externally located and accessible to the eye. The nutrition of the skin, like that of other organs, is entirely subordinate to certain nervous filaments, which regulate the tonus of the bloodvessels, and are therefore called vasomotor nerves. The disorders of the nutritive processes of the skin clearly manifest the derangement of the nervous elements connected with the affected region of the skin, which really constitutes the effective cause.

The arteries and the veins are subject to variations in caliber not only in a passive way, from their elasticity, but also actively from the presence of muscular fibers in their coats. The muscles belonging to the organic system are exclusively under the control of the vasomotor nerves, which are principally supplied by the sympathetic nerve from the whole extent of the spine and from some portions of the base of the brain. It is well known that when one of these nerves is cut through, the temperature of the related part of the body rises, the arteries become engorged, and the pressure of the blood is augmented. On the contrary, the application of a galvanic current to the same nerve produces diminution of the caliber of the arteries and the temperature falls. This shows that the influence of the nerves on the bloodvessels is persistent, and through them the muscles of the vessels are continually kept in active tension. In the arteries the contractility is

[1] Read in the Section of Dermatology and Syphilography of the American Medical Association, at Detroit, June, 1892.

much better developed than in the veins, but in the small veins and in the capillaries, by lack of muscular fibers the changes in their caliber are only passive. The organic contractility of the arteries is not in relation with their pulsation, and in consequence their contractile power is the regulator of the pressure of the blood. These nerves control the nutrition of the different organs by increasing or diminishing the supply of blood, according to the energy and the activity of the organ.

The action of the vasomotor nerves on the muscular fibers of the bloodvessels explains many affections of the skin attended with inflammatory symptoms and changes in its nutritive functions. These affections have nothing to do with the real inflammations of the skin, and in most cases they are the result of some constitutional disorder, often of the presence of a poisonous substance acting upon the center of the vasomotor nerves. Exanthemata and many erythematous eruptions belong to this group and form a class named by Auspitz angio-neurotic eruptions.

It is not this kind of skin-affection that forms the basis of this paper, but I wish to speak of some disturbances in the nutritive functions of the skin manifested by intrinsic alterations of its histologic elements. There is no doubt that the nerves regulating the circulation, and presiding therefore over the nutrition of the skin, have a close relation with the sensory nerves, as tropho-neurotic disturbances are often consequences of irritation of the sensory nervous fibers, or are accompanied by alterations of sensibility.

In most cases we find that the lesions of the skin are accompanied by symptoms emanating from the nervous centers.

Miss V. B., a brunette, twenty-two years old, for about six months had noticed a peculiar eruption on her body. She appeared to be in good health. Menstruation was regular. When four years old she began to suffer with chorea, which lasted for several years. At the age of twelve she had epileptic attacks, which were repeated from two to three times a week. These subsided, but she remained subjected to attacks of dizziness and cephalalgia. She presented an eruption consisting of macular spots from the size of a dollar to that of the palm of the hand, of white, ivory color in the middle, surrounded by edges uniformly pinkish-red. The white of the spot presented the characters of a scar. The skin could not easily be raised between the fingers, being rather hard. The pinkish-red edges were not elevated above the level of the skin, and displayed no inflammatory manifestations. One spot, as large as the palm of the hand and somewhat oblong, was located on the right hip-joint. Another spot was on the abdomen, extending down to the genitals. Another spot, somewhat roundish, was on the left thigh. There was no pain or itching, but the spots presented a kind of numbness which caused some discomfort. The sense of touch on the spots was diminshed.

The case was one of liodermia neuritica, Glanzhaut, glossy skin, recently described as striæ or maculæ atrophicæ. Descriptions of this affection have been given by Cantani,[1] Feré et Quermonne,[2] Touton,[3] Buchwald,[4] Bradshaw,[5] Troisier,[6] Bouchard,[7] Wilks,[8] Sheperd,[9] and Ohmann-Dumesnil.[10] Almost all authors are agreed that the origin of the striæ or maculæ atrophicæ must be found in some tropho-neurotic disturbance. Sheperd and Ohmann-Dumesnil have each reported a case of liodermia consecutive to typhoid fever, and the latter ascribes the disturbance of the skin to the depressant action of the severe disease.

In my case disorders of the nervous system had been present; the patient at first suffered with chorea, then with epilepsy. Furthermore, the alteration of sensibility was very pronounced. I was not allowed to make a microscopic examination of the abnormal skin. There is no doubt, however, that the affection was the result of a disturbance of the nutrition of the connective tissue of the corium causing the peculiar atrophy by a defect in the action of the trophic nerves.

A not less interesting condition of the skin is the atrophy of the pigment, leukodermia, which I have likewise found associated with affections of the nervous system.

Not long ago, Mrs. A. T., thirty-nine years old, in rather poor health, sought relief on account of some white spots upon the face and trunk. She was of dark complexion, had dark hair, was very delicate and nervous, and her mucous membranes showed her anemic condition. Her appetite was usually not very good, and her bowels rather constipated. Menstruation was scanty and painful. She had at several times been under treatment for melancholia. She often had hysterical attacks, in the course of which she noticed a white spot on the left side of her chin, consisting of three or four coalescent maculæ, each as large as a quarter of a dollar, and extending from the left angle of the mouth toward the neck. The naturally dark complexion of the patient contrasted strongly with the white color of the spots. Other irregular spots could be seen on the neck and chest, on the arms and hands The spots were accompanied by no symptoms whatever, no itching, no pain, no desquamation, but in the affected regions

there was a great diminution of sensibility; there was likewise analgesia on her fingers.

According to Jacob Halpern,[1] in the regions of the human skin abundantly furnished with pigment the granules are mostly contained in the deepest layers of the rete Malpighii, and there are ramified ameboid cells which are connected with the blood-vessels and the nerves. The pigment in the white race consists of small granules of dark-yellowish color surrounding the ramified cells; no pigment-granules are found free in the layers of the epidermis without accompanying those cells which supply the pigment. This observation affords us the explanation that when the nutrition of these ramified cells is withdrawn their protoplasm is reabsorbed and they can no longer supply pigment-granules, and the pigment is reabsorbed by the cells of the rete. Pigment is nothing more than the result of a chromatopoietic function of these ameboid cells, which take up the blood-corpuscles or their contents, changing them into pigment, which is distributed in the layers of the rete and the deepest layer of the epidermis. In the appearance of the white spots of leukodermia we can see some relation with the distribution of the bloodvessels and the nerves in the affected region.

The neuropathic origin of leukodermia is supported by the analogy with lepra. In some cases of lepra we have leukodermia in the form of white spots, on the neck and on the extremities, and in the middle of the white spots sensibility is remarkably diminished. As lepra stands in such conspicuousness in relation with disease of the nervous system, it cannot be doubted that the affected nerves are responsible for the disappearing of the pigment in the affected regions by the disturbed action on the blood-vessels.

Another form of disturbance of the skin that I have encountered in association with nervous disorders is sclerodermia.

E. S., a German girl, eight years old, in infancy suffered with pneumonia, cholera infantum, and eczema, from which she recovered. About four years ago she began to be nervous and restless. She could not sleep, and cried without cause. At times she suffered with neuralgic pains in the legs and arms, and at times a severe itching sensation caused her to scratch and abrade the skin with her finger-nails. The parents remarked that her legs were getting thinner, and that the skin of the knees and calves was so hard and inelastic that the girl could walk only with great difficulty. Similar changes were observed in the arms and hands, until the girl could not move her limbs, which were perfectly stiff. The itching was so intense that the child could not get an hour's sound sleep. When I saw her she was rather well developed. Her face only presented some freckles in the region of the nose and cheeks. The hair was rather abundant, and of light-chestnut hue. Nothing abnormal was to be seen on her neck. The arms were thin, and the skin was so hard that the arms and hands could not be moved. The skin had a dirty-yellowish color, resembling parchment, from the deltoid region to the fingers. The elbow was stiff, and could not be bent. It was not possible to raise a fold of the skin, and it seemed that bones, muscles, and skin, formed one mass, like a piece of wood. The epidermis showed deep furrows, and especially on the hands around the wrists there were fissures from the breaking of the skin by attempts to bend the hands. No movement at all was possible in the fingers, which remained stiff and semiflexed. The pigment was unequally distributed on the affected surface, so that the color varied, resembling marble. There was a large area of sclerotic skin on her abdomen, extending from the left hypochondrium in a band to the genitals, which were also involved. The legs were in a similar condition. The right was the worse, and had lost its shape. It was stiff from the hip-joint to the toes. The left leg was affected to the knee, the thigh being almost free. The feet, like the hands, were hard and stiff, with some fissures around the calf from attempts to walk; locomotion was difficult and painful. The sensibility of the affected skin was greatly diminished. Itching was, however, marked, and the skin was excoriated from scratching. The skin was dry, and the perspiration was absent from the body, and only present on the head and face. The body temperature, taken in the affected axilla, was only 97·7°.

In this case there is no doubt that not only was the skin deeply affected, but the muscles had also undergone a certain degree of atrophy, as the limbs were deformed and movement interfered with. Changes in the muscular fibers in cases of sclerodermia have already been recorded by Thibierge,[1] who expressed the opinion that the affection of the skin is secondary to the affection of the muscles. In our case, however, the relation seems to have been the reverse. The atrophy of the muscles seems to have been secondary to the affection of the skin.

I am sorry not to have been able to make microscopic investigation of the affected skin, as this was refused by the mother of the girl. The disease seems to have had its seat in the connective-tissue elements of the corium and of the subcutaneous tissue. The panniculus adiposus was completely gone, from atrophy of the fat-cells, and the elastic fibers were greatly increased. The bloodvessels and the lymph-spaces were compressed by the accumulation of connective-tissue elements, which produced also the atrophy of the glands of the skin.

Here we have three affections of the skin that display an intimate connection with diseases of the

[1] Ueber das Verhalten des Pigmentes in der Oberhaut des Menschen. Monatshefte für prakt. Derm., 1892.

[1] Rev. de Médecine, No. 4, 1890.

nervous system. The first case, one of macula atrophica, was in a woman who was affected with chorea, and later with epilepsy; the second case, one of atrophy of the pigment, was in a woman, affected with hysteria and melancholia; the third case was in an extremely nervous girl, affected with neuralgic pains. There is nothing new in this proposition, but I only want to strengthen what has been already observed. Duhring[1] refers to atrophy of the skin in consequence of alteration of the nutrition in progressive muscular atrophy. Weir Mitchell[2] has reported cases of injuries of the nerves, with atrophy of the skin, and of the subcutaneous tissue. Robinson[3] is of the opinion that glossy skin may result from wounds. McCall Anderson[4] refers to a case of atrophy of the skin which followed an injury of the supraorbital nerve, and gives as the cause of the atrophy of the half of the face that took place the irritation of the sympathetic of the neck. Brunner[5] found atrophy of the skin of the left side of the face in a female epileptic.

Considering the condition of the nervous system in our patients, it appears that the cause of the disturbances of the skin have to be found in the nervous system. The action of the nerves is to regulate the functions of the bloodvessels. The alternations seem to have been especially in the sympathetic system, which presides over the vegetative functions, but we cannot absolutely assert that the nervous centers are not implicated in the production of these affections. Fibers from the brain and spine pass through the ganglia that constitute the origin of the sympathetic and make it an independent system. The fibers emanating from the ganglia are not only motor, but also sensory. This is made manifest when irritation is applied to a region under the control of the sympathetic nerves; movements are produced in the organs supplied from that group of nerves. The ganglia are not organs of movement, but are organs through which reflex action is accomplished without the consciousness of the brain. The stimulus applied to the sensory fibers causes a reflex movement through the ganglion, the sensation remaining in it without causing any feeling; but when the stimulus becomes an irritation, its effect does not remain limited to the ganglia, but is carried to the spine and to the brain, giving rise to pain.

Many disturbances of the nutrition of the skin exist without producing any sensation, remaining strictly limited in the zone under the control of the sympathetic. This we see when the disturbance does not deeply affect the texture of the skin, as in our cases of leukodermia and liodermia; but when the results of the affection are more profound, as in sclerodermia, then some sensation is aroused, as in our case, which was attended with neuralgic pains and itching. There is no doubt that some of these affections, by their topographic distribution in the skin, follow the ramifications of the nerves lying underneath, or rather follow the lines of division of the cutaneous nerves, as indicated by Voigt. In nevus linearis, ichthyosis cornea, ichthyosis hystrix, we find the disposition of the disease in the course of the underlying nerves. In one case of ichthyosis hystrix, in a boy eight years old, that came under my observation, the disease so closely followed the course of the sciatic and crural nerves that it looked as if some one had drawn the lines with the pencil. In many cases of anomalies of the pigment, as in nevi pigmentosi, either congenital or acquired a short time after birth, the lines follow the ramification of the nerves of the affected region with wonderful closeness. Kaposi refers to two cases of nevi verrucosi, in which the verrucæ were seated accurately in the course of the sciatic nerve.

Neumann[1] refers to a case of nervous nevi, in which the pigment-hypertrophy and warts were distributed from the gluteal region to the toes of the foot, in perfect correspondence with the nervous ramifications of the leg. The disposition of these maculæ, or hypertrophies of the epidermis, corresponds with that of the underlying superficial nerves, but does not exactly follow the deepseated nerves. According to Philipson,[2] the skin-disturbances follow rather the cutaneous nerves, maintaining the lines of Voigt. The difference of direction between some lines of altered skin and the direction of the nerves would be explained by the physical growth of the body, the affection occupying the original course of the nerves.

The nerves that control the nutrition of the skin are not distinct from others, but are in connection with motor and sensory filaments. In consequence of this fact Baerensprung considered alterations of the skin of this kind as the result of a disturbance of the spinal nerves. The same nervous origin applies to nevi vasculares, in which the spots represent areas corresponding to the distribution of the nerves of the region. Nevus vascularis of the face indicates that originally, in the embryo, the trigeminus was affected, with dilatation of the capillary bloodvessels as a result.

In our first case we have two areas of the skin affected with atrophy in an oblong form. There was at first a small spot of a reddish-violet color, which gradually became white and atrophic in the center,

[2] Monatshefte für prakt. Dermat., 1806.

showing the intense color in the periphery. The intense redness was the result of stasis due to the diminished tonus of the bloodvessels, the vasomotor nerves having lost their control.

In the second case, we have atrophy of the pigment following the course of the inferior maxillary nerve of one side and on the left arm.

In the third case, there were profound alterations of the skin involving the corium and the subcutaneous tissue, due to the condition of the nutrition of the limbs and body.

All three affections appeared and slowly progressed in persons affected with nervous symptoms, as anesthesia, analgesia, hyperesthesia, etc.·

I believe that liodermia, leukodermia, and sclerodermia, although different affections, are closely related. They display an affinity for persons with an altered condition of the general nervous system.

They are the result of an affection of the nerves, either central or peripheral. In a word, they are the result of an alteration in the nutrition of the skin, through an altered condition of the trophic nerves.

In conclusion, I would say that the difference between leukodermia, liodermia, and sclerodermia, is only one of degree, produced by lack of nutrition, affecting in the first the ameboid cells of the Malpighian layer, which furnish the granules of the pigment; in the second, affecting the connective tissue of the superficial layer of the corium; and finally, in the third, involving the connective tissue of the corium and of the subcutaneous tissue.

INTUBATION VERSUS TRACHEOTOMY.

Being a Study of 858 Cases Operated On at the Boston City Hospital.

By ROBERT W. LOVETT, M.D.,
of Boston;
out-patient surgeon to the Boston City Hospital; assistant surgeon to out-patients at the Children's Hospital, and surgeon to the Infants' Hospital.

The operation of intubation for the relief of croup is one that has excited the deepest interest in the last few years, and its merit is a question of the greatest practical value. It comes into competition, of course, with the older operation of tracheotomy, and the question of the comparative merits of the two is one that has been the subject of many articles. At the end of six years of trial, during which time the operation has been performed upon thousands of cases, intubation stands in a position to be judged on its merits, and to be compared with the operation of tracheotomy as a life-saving measure.

There are two methods of presenting this comparison to the reader: (1) By the relation of personal experience and by weight of authority[1]; (2) by the statistical method, which is open to the objection pertaining to all statistical inquiries in medicine, but which, upon the whole, seems to me to be a more scientific and satisfactory mode of procedure.

The objection to any method that collects reported cases of the two operations from literature and endeavors to draw conclusions in this way as to the comparative merit of the two lies in the fact that the statistics of either operation greatly vary according to locality and the individual reporter, so that in this way they lose much of their value from their lack of uniformity.

When groups of cases of tracheotomy, for instance, are collected from literature, the variation in the recovery percentage is a most striking one. For example: in 9242 cases collected from French authors the recovery percentage was 24, while in a group of 400 cases reported by Wauscher, of Copenhagen, the recovery percentage was 42. It is manifest that if any practical conclusions are to be drawn from the comparison of tracheotomy and intubation statistics, the two classes of cases should have been, to a certain extent, under like conditions. It is for this reason that I venture to call attention to two groups of cases, taken from the records of the Boston City Hospital, which seem to have more than a passing interest in determining the relative value of these two operations. I have nothing new to present in a statistical way, and merely desire to call attention to certain obvious deductions that seem warranted from the two groups of cases already reported from the Hospital. These deductions are, however, necessarily colored by my personal views and experience.

With regard to the opportunities afforded at this Hospital for such observation, it may, perhaps, be permissible to quote the remarks of Dr. O'Dwyer, in a letter to Dr. G. W. Gay:[1] "From the large number of cases of croup treated at the Boston City Hospital it certainly affords the best opportunity for the study of this disease to be found anywhere in this country. When you shall have accumulated the same number of intubations as you have had tracheotomies it will settle the question of the comparative methods of the two operations in saving life better than thousands of cases collected from various sources."

Up to the year 1887 the operation of tracheotomy was the only one performed at the Hospital. The cases from 1864 to January, 1887, were collected and analyzed.[2] Of these cases there were 327. Excepting in 30 cases, all of the operations were done between 1880 and 1887. The first intu-

[1] Faulkner: The Medical News, April 9, 1892.

[1] G. W. Gay: Boston Medical and Surgical Journal, October 11, 1888.

[2] Lovett and Munro: The American Journal of the Medical Sciences, July, 1887.

bation was done at the City Hospital, December 31, 1886, and from that time to January, 1891, the operation was performed 392 times.[1] It seems perfectly fair to contrast these two groups of cases as bearing upon the merits of the two operations, because they were performed under like conditions, upon the same class of cases, and, for the most part, by the same surgeons. The operation of intubation was taken up with interest, and was most carefully watched.

It should be borne in mind that the cases included in these two groups are, for the most part, severe cases. The Hospital is particularly well equipped for the care of these cases of diphtheria, and, in general, cases are sent to the Hospital in preference to being operated upon at home. At the same time it is easy to see that the cases are sent to the Hospital generally as a last resort, after the expectant treatment has been pursued in most cases too long, and the children who are admitted to the surgical department of the Hospital are only too often in a hopeless condition. As mentioned by Dr. Gay, it has always been the policy of the Hospital to perform the operation, even in manifestly hopeless cases, in the hope of affording relief. It cannot, therefore, be expected that the mortality percentage will be a low one when such a class of cases is taken for analysis; nor, as a rule, would the results be nearly as favorable as in private practice, where cases are likely to be seen earlier, and where mild cases would be seen. The proportion of cases developing laryngeal symptoms in the Hospital is a small one, and most of the cases are admitted in a state of urgent dyspnea.

For the most part, the conditions from 1880 to the present time have been constant. If there has been any change, it has been since February, 1888, when a new diphtheria-ward was opened, which is particularly well equipped and well ventilated, so that it would seem probable that any change in the conditions would tell in favor of the later operation of intubation. Since July, 1890, two house-officers have been detailed for exclusive duty in the contagious service, serving two months, and living in the ward. If there is any fault to be found with the results of either operation at this Hospital, it is not to be ascribed to unfavorable conditions or inefficient nursing. The conditions are as favorable as possible.

After this prelude, it may be permissible to examine in detail what the results of the two operations have been, as exemplified by the figures taken from the books of the Hospital. Up to 1887, tracheotomy had been performed in 327 cases for croup. Of these cases, 232 died, and 95 recovered, making a recovery percentage of 29.05; ten cases died during or soon after operation, but only four of these from hemorrhage. It was manifest from a study of these cases that the tracheotomy death-rate at the Hospital continued for months in closest correspondence with the mortality percentage of diphtheria in the whole city of Boston. In short, when diphtheria was most fatal in the city tracheotomy was most fatal at the Hospital. It is presumable that the same conditions could be applied to intubation, although it has not been possible to analyze the cases in this regard. It must, however, be evident to anyone who sees many of these operations that it is the severity of the disease that kills in most cases rather than any influence related to the operation itself.

In the 327 cases of tracheotomy there were four in which it was difficult to remove the tube. Several months elapsed before it could be permanently taken out. All of these cases completely recovered.

In short, tracheotomy was performed 327 times, with 29.05 per cent. of recoveries; ten cases died immediately, presumably as the result of the operation, and in four cases there was difficulty in removing the tube.

The first intubation at the Hospital was performed on December 31, 1886, and from that time until January 1, 1891, this operation had been done 392 times. During this time 139 tracheotomies were performed. It is manifestly unfair to consider these tracheotomies as having any bearing upon the question at all, because, in those four years the operation of intubation was adopted as a routine procedure, so that tracheotomy was reserved for the most part for the severest and most desperate of the cases, in which it seemed hopeless to do intubation, so that these 139 operations, in which the recovery percentage was only 11½, cannot be taken into account in any way. It is not by this meant that the cases of intubation were selected, but that, naturally, tracheotomy, as the old and more tried operation, was adopted as a last resort in the severest cases. When it is noted that nineteen of these tracheotomy cases were moribund at the time of operation it can, perhaps, be better understood how desperate the majority of them were.

Of the 392 cases of intubation, 312 died, and eighty recovered, making a recovery percentage of 20.41. The accidents occurring in connection with tracheotomy have been mentioned, so that it seems perfectly fair to speak of the more numerous accidents in connection with the operation of intubation. Twenty-one times intubation was attempted, and immediate tracheotomy was necessitated by the cessation of breathing. Of these cases only two recovered. In three cases death occurred during the attempt to insert the tube. Two children died during the choking-spells. In two cases the tube

[1] Prescott and Goldthwaite: Boston Medical and Surgical Journal, December 31, 1891.

was drawn into a bronchus, and death of course resulted. In two the insertion of the tube was followed by convulsions. In two the introducer broke during the operation. This list of accidents, all necessitating tracheotomy, it seems to me, is a serious commentary upon the operation of intubation.

It is no easy matter to do an instantaneous tracheotomy when an intubation tube has been introduced and has failed to give relief, or when the attempt at intubation has caused sudden choking. The child is generally lying in bed, the cessation of breathing is instantaneous and very threatening, and the conditions are not favorable for the careful and successful performance of tracheotomy. The fact that only two of twenty-one cases of this sort recovered is not encouraging for the performance of such operations. The operations were performed with care, and under otherwise favorable conditions, inasmuch as they were undertaken in a well-equipped hospital, so that the liability to accident should have been certainly no larger than in private practice.

In two respects, then, intubation does not compare favorably with tracheotomy in the study of these two series of cases: 1. The death-rate of intubation is 9 per cent. higher; 2. Accidents during intubation are much more common.

It is of especial interest to consider the merits of the two operations with regard to children under three years of age. The outlook could hardly be worse than it is in tracheotomy. Of forty-two patients under two years of age, on whom tracheotomy was done, only three recovered, while, of 123 cases in which intubation was performed on children under three years of age, 14.63 per cent. recovered. Although these two groups of cases cannot be very well compared on account of the differences in age, yet if an operation is so nearly hopeless as is tracheotomy, it seems wiser to perform the milder operation of intubation. Again, tracheotomy in these very young children is likely to be a difficult operation, and, although intubation is by no means easy in these small mouths, it seems to me to be a more acceptable operation than tracheotomy in children under two years of age. In children between two and three the question would be debatable. With regard, however, to the choice between the two operations in general, the question is often evaded by the performance of intubation, to be followed by tracheotomy. Should the case progress badly, it is against this secondary tracheotomy that I would particularly protest. I would plead for the early performance of tracheotomy if it is to be done at all.

The showing for this secondary tracheotomy is exceedingly bad when the figures are considered. In the City Hospital figures there were 57 secondary tracheotomies, with 5 recoveries. Ganghofner[1] has reported 21 late tracheotomies in 42 cases of intubation, all of which were fatal. Urban[2] lost all of 18 secondary tracheotomies done after 32 intubations. Jakubowski did 27 secondary tracheotomies in 64 intubations, and 25 died. Mudd[3] saved 3 out of 4 secondary tracheotomies.

These are all the reported groups of secondary tracheotomies that I have been able to find, but as a collection they afford very little encouragement for secondary tracheotomy, whatever the cause may be of this great fatality:

	Secondary Tracheotomy.	
	No. of cases.	Recoveries.
City Hospital	57	5
Ganghofner	21	0
Urban	18	0
Jakubowski	27	2
Mudd	4	3
Total	127	10

The recovery percentage was 7.8, and without Mudd's very exceptional group only 5.8 per cent. recovered.

To commit oneself to a method of procedure of which the recovery percentage in cases of average severity ranges from 6 to 8 seems unjustifiable. In view of these figures the conclusion that I would present is that intubation is not so favorable an operation as tracheotomy for the saving of life in severe laryngeal diphtheria. The chief reason for this appears to me to be twofold: intubation does not afford such good drainage to the trachea, and only a limited amount of nourishment can be taken by the intubated patient.

First, as to drainage. A child on whom tracheotomy has been performed expels through the tube large quantities of detritus, consisting of mucus, pus, and diphtheritic membrane. The metallic expulsive sound with which this is ejected is familiar in every tracheotomy-room. The stuff comes out, often a teaspoonful at a time, for two or three days, and the larger the amount of discharge the more favorable the outlook for recovery.[4]

In intubation cases this does not occur. Whatever becomes of this mass of material, it is certainly not expelled from the mouth. It may be swallowed or it may be inhaled, but it is not often expectorated. To my mind this is a great disadvantage, in comparison with which the occasional accidents associated with intubation are of little account. The material is highly septic, and its retention in the body cannot be otherwise than harmful. This is a

[3] Medical Mirror, January, 1890.
[4] The American Journal of the Medical Sciences, July, 1887.

matter that has been largely overlooked, but which is certainly of consequence in severe diphtheria.

The limited amount of food that most cases of intubation are able to take is also to my mind a decided objection to the operation in severe diphtheria. In the tracheotomy series the children took from twenty to forty ounces of milk a day. Thirty ounces constituted a fair amount, and when a child took less than twenty-five ounces it was noted as an unfavorable symptom. In the intubation cases the diet was retricted to soft solids, which are inferior to milk in their sustaining power, and a much less quantity was generally taken than was the case in the tracheotomy series. A diet of soft-boiled eggs, milk-toast, ice-cream, and oatmeal, is not a stimulating one, nor is it one very well suited to maintain the strength throughout an intensely septic and prostrating disease. Rectal injections can of course be used to supplement feeding by the mouth, but only a limited amount of food can be taken in that way, and often none at all is retained. It has been said that it is the severity of the disease that kills in most cases, whatever the operation, and the free stimulation possible in tracheotomy cases is often a powerful aid in withstanding the great prostration and sepsis. To give up the hourly stimulation of concentrated food and alcohol, pushed to its utmost, is to my mind to give up a very important means of doing good in these desperate cases.

Most of the objections so often urged against intubation seem trivial in the extreme. The fact that the lumen of the tube is smaller than the normal trachea, that tubes are occasionally coughed out or swallowed, the fact that food is occasionally drawn into the trachea, are matters of small moment. Intubation tubes become stopped with membrane often, but so do tracheotomy tubes. These are comparatively trifling matters.

When, however, an operation shows a recovery percentage of nine less than the operation that it is intended to supersede, in presumably the same class of cases, it becomes time to criticise it, and, if possible, to find the source of the greater fatality.

In conclusion, I would again call attention to the lamentably small recovery percentage in cases in which tracheotomy has been performed after a preceding intubation. Again, accidents, and especially hurried tracheotomy, occur often during attempted intubation. In most cases these eventuate fatally.

Finally, I would suggest that the cause of this increased fatality after intubation in severe diphtheria lies in the imperfect drainage and the limited amount of nourishment that it is possible to give.

The performance of any operation as a routine practice is of course unfortunate, and individual cases should be treated according to their especial features, but in general I would be glad to advocate the performance of tracheotomy instead of intubation in most cases of severe laryngeal diphtheria, except in the cases of children under two years, when intubation is to be preferred.

ORIGINAL ADDRESS.

THE RELATIONSHIP OF DISEASES OF THE LOWER ANIMALS TO MAN.[1]

BY JAMES LAW, F.R.C.V.S.,
PROFESSOR OF VETERINARY MEDICINE, CORNELL UNIVERSITY, ITHACA, N. Y.

I ACCEPT the invitation to address you on this occasion as a tribute to the growing sense of the value of comparative medicine in the sanitary field. I shall therefore ask your attention shortly to a few points showing the relationship of diseases of the lower animals to the well-being of man.

A sense of the dangers attendant on the use of animal food appears to have been almost as old as history. The law of Moses distinguishes between the clean and the unclean, the beasts that may be eaten and those that may not. The prohibited animals are, in the main, the purely carnivorous and omnivorous — those that are especially liable to contract contagious and parasitic diseases from the flesh of their victims. In drawing a safe limit, the edible mammals were practically restricted to the ruminants, which are *par excellence* herbivorous. According to this law, however, even the *clean* animals were forbidden, if they died of disease, of strangulation, or with the blood in the carcass. Similarly, among many primitive peoples a dead body is tabooed, and in ancient Greece the priests of Zeus were polluted by touching uncooked meat.

The great sanitary importance of the Mosaic laws for a pastoral people pitching their tents on the open, grassy plains, and living, in a sense, in common with their vast flocks and herds, is manifest without argument. The parasites and contagia that they mutually harbor increase and dominate in exact ratio with the close aggregation of their hosts—human and brute—and the facility of their transmission from one to another. The prohibition falls first on those flesh-feeders that are the most likely to reciprocate with man in the maintenance of parasites and infections. Then it denounces the sick as especially dangerous, and, finally, that which dies full of blood and is correspondingly liable to early putrefaction. The prohibition of blood was probably ritualistic rather than sanitary in its object, yet we need not ignore the experiments of Signol, who showed that the portal blood of a suffocated horse contained a poison that could be conveyed from horse to horse with fatal results through several successive generations.

The simple avoidance of the dead body and of uncooked meat in the case of many early peoples, though showing a similar precautionary tendency, is far less effective than the prohibitions of the Jewish code. We can still observe the good fruits of the latter in the comparative immunity of the Israelite from such diseases as trichinosis, the pork tapeworm, and tuberculosis.

These examples of tribal hygienic laws, however well-

[1] Delivered before the Alumni of the University of Buffalo.

suited to an age in which the knowledge of disease and its causation was but as a glimmering spark, are sadly antiquated and ineffective in the strong electric glare of the nineteenth century; yet even now our hygiene of meats, as applied to our stockyards and markets, is far behind that which the Jews have practised for over three thousand years.

The Jewish system is a crude measure, feeling, as it were, in the dark for protection from an imminent danger, and was perhaps as perfect as could be understood by a people with the grade of knowledge possessed by the Jews; but it is capable of making no real discrimination between the dangerous and the harmless—whole genera of wholesome animals are prohibited to avoid the danger of a few of each genus conveying deadly poisons; and the wholesome flesh of the imperfect or injured animal is condemned equally with that which is the subject of a fatal infection. Moreover, some of the most deadly diseases (like anthrax), affecting the blood and spleen only, may still pass as wholesome, because no solid tissue of the body has been observed to be diseased.

With our modern knowledge of the life-history of parasites and of the microbes of disease this crude and unintelligent selection and rejection must give place to a true scientific scrutiny; and every available resort, microscopic and otherwise, must be brought into requisition to protect the public from the truly dangerous animal foods.

To illustrate the field that must be covered I shall name a few of the diseases of our meat-producing animals that are communicable to man, and I cannot begin the list better than with

TUBERCULOSIS.—From this terrible scourge the sheep is almost exempt, while cattle, goats, pigs, rabbits, and chickens are extraordinarily susceptible. Among many wild animals also, the proclivity is strong, and thus at every hand man is liable to meet the redoubtable bacillus. The dangers of the disease are the greater that in many cases occurring in man and beast it assumes a chronic course, and its victims manifest a fair measure of health, so that their unsuspecting owners apprehend nothing and see no need of disposing of them, and of thus cutting short their career of plague-diffusion. The vitality of the tubercle-bacillus is also very great, so that it survives alike the lapse of time, the wetting, drying, freezing, and thawing of changing seasons, and even the curing of the meat and the heat of ordinary cooking. Toussaint and others have again and again infected animals with meat that was believed to have been sufficiently cooked for safety. The dried-up expectoration is easily diffused with deadly effect on the air, to be inhaled by man and beast; and though for man perhaps the most common vehicle is the handkerchief, and for the beast the feeding or drinking trough, yet the dust of of our streets and stock yards, of our dwellings, stables, passenger and stock cars is a prolific channel of infection.

Milk is another common medium of infection, and, since the time of Gerlach, has been often used successfully to produce tuberculosis in previously healthy animals. Nor is the local disease in the udder essential to its conveyance through the milk. The tuberculous cow, with a still apparently healthy udder, frequently yields milk which, inoculated in other animals, produces tuberculosis. Irrespective of the escape of the microbe with the milk, however, it is a thousand to one that the tuberculous cow in licking her udder should leave upon it more or less of her infecting expectoration, to be dropped into the milk-pail as dust at the next milking. A frequent mode of propagation among pigs must not be overlooked. About abattoirs it is a common practice to feed to pigs the uncooked offal of the slaughtered animals. As in certain districts a considerable proportion of the cattle are tuberculous, this amounts to a systematic infection of the hogs. A few years ago, at a large public institution, where one-half the herd of cattle proved to be tuberculous, and where the pigs were fed on the offal of these cattle killed for beef, I found that the swine were, as a rule, similarly affected. I am informed that it is no uncommon thing here in New York for a cow, run down by tuberculosis, to be butchered in some out-of-the-way place, cut up into mince-meat, and put on the market as sausage.

Then, again, the danger of contamination through offal and expectoration, though great for pigs, is even greater for chickens, which secure admission to every yard, and eat indiscriminately any organic refuse they can find—notably thick expectoration. Then, too, the course of tuberculosis is far more virulent in the chicken than in our larger mammals, and the product is proportionately infective to other animals. Is it wonderful that in the State of New York for a period of eight years ending 1888, every eighth death was from tuberculosis? We need not ignore or undervalue the accessory and predisposing causes of this dread disease. Many persons have undoubtedly a great power of resistance to tuberculosis, and the great majority escape death by this all but ubiquitous germ; yet the facts remain that none contracts the affection in the absence of the bacillus; practically no efficient measures are taken to restrict its prevalence, and 12 per cent. of our human mortality is caused by its ravages. Now, one word as to the diagnosis of tuberculosis in animals. Speak of consumption, and the average hearer conjures up a vision of extreme emaciation, a frequent, racking cough, profuse expectoration, with solid particles floating in a purulent medium, a heavy and somewhat offensive breath, inappetence, sunken eyes, and general wretchedness. In cattle, however, the majority of cases show no such symptoms, at least for a length of time—often for years—after the onset of the disease. The symptoms will vary extremely, and prove in the main absolutely unlike in different cases, according to the organ attacked. I cannot take time here to enumerate the symptoms of the different forms, so I shall content myself with naming the organs most frequently attacked, to the exclusion of the lungs:

1. The bowels and mesenteric or sub-lumbar glands.
2. The throat and pharyngeal lymphatic glands.
3. The liver, spleen, pancreas, or kidney.
4. The generative organs (ovary, womb, testicle).
5. The subcutaneous and intermuscular lymphatic glands.
6. The cancellated tissue of the bones.
7. The skin.

As the involvement of each of these may assume all grades of severity, it must be evident that great skill is required to diagnosticate many a chronic or subacute

case of tuberculosis in the animal. In many occult cases, indeed, diagnosis is practically impossible by ordinary tests, and in the case of dairy herds in particular the reaction with tuberculin may be invoked to attest whether the milk-supply is wholesome or otherwise. Inoculations may further be resorted to in doubtful cases. These tests, however, together with the post-mortem examination in the abattoir, with the occasional resort to staining and microscopy, can only be conducted by the educated man.

To properly restrict such a disease as this, and to prevent its propagation to the human family from the brute, a professional supervision of dairy herds is demanded; also, of stock yards, but above all of slaughter-houses, and to make this last effectual every town should have its *one* municipal abattoir, where alone animals may be killed and where every animal killed must be inspected. Meat that has not been inspected by the authorities should be debarred from the market.

ANTHRAX.—To turn to another animal contagion—*anthrax* may be selected. Though most deadly to both man and beast, this, when once started, is not propagated indefinitely in a locality. Its germ—the bacillus anthracis—is one of the largest of the pathogenic microbes, and was the first to be identified as a cause of disease. The disease is rarely propagated except by contagion from diseased animals—either directly, or through the medium of flesh, blood, morbid discharges, hair, wool, hides, bones, litter, knives, or other solid bodies that have been stained with the diseased products. Its perennial home is in certain dense, wet, or septic soils, in which its spores are preserved indefinitely, and which prove deadly to flocks or herds placed upon them. In open, well-aired soils it is soon rendered harmless. In man it is largely the disease of herdsmen, cattle-dealers, butchers, tanners, hair-workers, felters, and wool-sorters, and, exceptionally, through the contaminated flesh, milk, or cheese of consumers. Though this wholesale poisoning of men is exceptional, yet on infected soils it sometimes reaches a high figure. In 1770 15,000 people died in six weeks in St. Domingo from eating anthrax flesh, and in the frequent anthrax years on the steppes of Russia a large percentage of the human population often perish in a single year. Besides this, the virus is carried and inoculated by mosquitoes and other blood-sucking insects, and thus man is usually attacked on the face, hands, and arms—the parts which are habitually bare. The dangers to man are, therefore, coextensive with the prevalence of anthrax in animals. Anthrax may, however, appear as a general fever, with no local external lesion, or it may become localized in tongue, throat, bowels, skin, muscles, lungs, or elsewhere, and according to its seat will be its symptoms and morbid changes. At the autopsy the engorged spleen may indicate disease, but it requires professional skill to say whether that engorgement is due to the bacillus anthracis, the shorter bacillus of blackquarter, a bacillus of septicemia, or the plasmodium of Texas fever. From Texas fever, however, man is exempt, and he can eat the flesh of its victims without thereby sealing his fate.

BLACKQUARTER, or bloody murrain of cattle and sheep, has been alleged to be incommunicable to man, as anthrax has been said to respect swine, but there is a sufficient number of instances to the contrary to show that the immunity is by no means invariable.

DIPHTHERIA.—It may be a revelation to some that that dread of our nurseries—diphtheria—is also a disease of the lower animals, and that, among other parts, it attacks the udder and milk-ducts of cows, and thus through the medium of the milk it can find an easy entrance to the throats of children. Whether, therefore, in the dairy cow or in the slaughtered ox, the educated eye should be ready to detect and remove the animal charged with such a terrible infection.

GLANDERS is usually supposed to be confined to the horse and man, and in both alike it is rightly considered one of the most painful, loathsome, and fatal diseases. It can be successfully inoculated not only in man and the horse, but also in the sheep, the goat, the pig, the rabbit, the dog, and the cat. The meat-inspector must, therefore, be acquainted with the affection as it occurs in each of these genera, and as it attacks the different regions of the body; for glanders may attack almost any portion of the system, to the exclusion, at first, of its common seats, the nose and skin. In this disease, too, as in tuberculosis, the germ (*bacillus mallei*) elaborates specific chemical poisons (ptomaïnes and toxines) which, when inoculated in the suspected animals, go far toward determining the presence or absence of the disease, by producing or failing to produce a febrile reaction in the subject. Again, as in tuberculosis, the germ of glanders can be cultivated on a large number of organic substances, as bread, potatoes, peptonized gelatin, etc., outside of the animal body, and hence its tolerance in any locality is a source of constant danger, and, in the present state of knowledge, nothing less than criminal.

CANINE MADNESS.—As we erroneously attach the idea of glanders among domestic animals to the horse only, so we connect the idea of rabies (hydrophobia of man) with the dog. Not man alone, however, but all domestic animals contract this disease when inoculated with the mad dog's tooth, and in all alike the carcass becomes infecting. I must add that the disease does not always present itself in the violent or delirious form, but that in a certain number the apathetic or paralytic symptoms predominate from the first, and in the absence of an intelligent inspection the meat of such an animal may be thrown upon the market and may fatally infect those that partake of it. That this disease can be prevented by inoculation with the toxines has been shown by the admirable work of Pasteur; yet the enthusiastic application of his method to the as yet sound animal is not without its drawbacks and dangers, unless the animal so inoculated is carefully secluded from others for a length of time. It is a notorious fact that where such inoculations have been most extensively adopted rabies has been unusually prevalent in animals, a circumstance that calls for intelligent supervision of our meat-products in this direction.

TETANUS, or LOCKJAW, is nearly related to rabies. Its germ (*bacillus tetani*) is conveyed from infected soil to man or beast, and from animal to animal indefinitely. Like rabies, it makes its localization in the great nerve-centers, as the general racking muscular spasms bear all too frequent evidence. Like rabies, too, it attacks all warm-blooded animals, and thus man may suffer by infection from any creature so diseased, or from contaminated dwellings, instruments, or soil. While it is true that this malady can be cured by the blood-serum of an

animal that has survived an attack, and while it is further true that the system may be fortified against it by inoculation with the ptomaïnes and toxines produced during the disease, such truths can never justify the lack of such skilful professional inspection of our meats and meat-producing animals as shall protect the community from an affection at once so agonizing and so redoubtable.

MILK-SICKNESS.—In a number of localities that have fallen behind in the race of agricultural improvement there lingers a disease, indigenous to the soil, communicable to all mammals and affecting the nervous centers so as to nearly abolish the functions of the brain and spinal cord. It produces, among other things, profound torpor of the digestive functions, general nervous tremors, loss of control of the voluntary muscles, and great depression of the intellectual functions, amounting in man to loss of the moral sense. If survival takes place at all, it is at the expense of rational and moral qualities, as a result of which continued existence is rendered altogether undesirable. A dangerous feature of this disease is that, if it attacks a milch-cow, most of the poisonous products are secreted in the milk, and the cow shows only slight signs of illness. The contaminated milk, butter, and cheese, however, prove most pernicious to those who consume them; hence the disease is known as *milk-sickness*. Physicians practising in *milk-sick* districts say that such cases are not altogether absent from our large cities, being caused by the meat, butter, and cheese shipped from such contaminated districts, and that certain obscure cases of intestinal torpor, brain-prostration, and mental hebetude are to be thus explained. It is true that milk-sickness is an affection confined within very narrow limits, yet, like other deadly contagia, it could be largely obviated by a strict municipal professional control of all meats offered for sale.

FOOT-AND-MOUTH DISEASE is fortunately not a present denizen of this continent, but, when it does secure a footing on our shores, it threatens all mammals, and through the contaminated milk is liable to carry off our children by an acute digestive disorder.

ACTINOMYCOSIS, the LUMP-JAW of cattle, is common in man and other animals, attacking not the jaws alone, but the tongue, face, throat, abdominal organs, the walls of the chest and belly, and even the brain. As the disease is due to a slowly growing cryptogam, it has been common practice in Europe to cut off the diseased portion and put the remainder of the carcass on the market *as sound beef* forsooth. Some great feeders and packers connected with the Whiskey Trust are contesting in the courts of Illinois their right to do the same. A sound sanitary system, recognizing that this vegetable parasite can only proceed from the seeds of a similar preëxisting growth, that the seeds from any such growth may develop when planted on any susceptible raw surface or follicular recess of the body, and that its presence in isolated form in such a secluded organ as the brain proves the conveyance of the seeds by the animal fluids, must recognize that the removal of the visible deposit is no sufficient guarantee, and that the condemnation of the entire affected carcass is demanded. It is quite true that the thorough cooking of the meat would render it wholesome, but the same remark would apply to trichinous flesh or to any meat in which the dangerous factor is a living organism. That man suffers extensively from the disease is witnessed by reports in the medical journals of from two hundred to three hundred cases in the course of a few years past. The danger is, therefore, far enough from being a merely imaginary one.

I need not try your patience by following this list further. I might speak of *malignant edema*, and other forms of *septicemia*, of *erysipelas*, of *pyemia*, of *gangrene*, of *echinococcus*, of the *beef and pork tapeworms*, of *trichinosis*, of the *infective osteitis* of young animals, and of still other infections and parasites that we reciprocate with our brute possessions. I might speak of the leukomaïnes and toxines of overexertion and excitement, and of the ptomaïnes and other poisons of decomposing and putrid meats, of the inoculation of live stock with animal venoms, of the impregnation of the flesh with vegetable narcotics, which though harmless to certain herbivora, are deadly to man, and of the presence of certain inorganic agents, which, like phosphorus, are most injurious to the human organism. I might go on to show that in all conditions of high fever and in various other forms of disease the flesh becomes unwholesome and innutritious. Finally, I might go over the whole list of zymotic diseases that respect the human family, but are contagious from animal to animal, decimating herds, depressing agriculture, and reducing the quantity and raising the price of meat.

I have said enough, however, to show that the comparative pathology of the end of the nineteenth century is such as to justify and demand a scientific inspection of our live stock offered for food or furnishing dairy-products, and no less so of carcasses presented for human consumption. By scientific inspection I mean, not the untaught glance of the man who has graduated from the stock yards, the shambles, or the army commissariat, but the skilful scrutiny of the professional man, trained in comparative pathology, up to date in the sciences of bacteriology and parasitism, and having at his command modern methods of work and instruments of precision. I cannot too much deplore the low estimate put by the public on such work. The political representatives of this State at Albany voiced the general ignorance in enacting a law giving the title of veterinary surgeon to all who would testify that they had prescribed medicinally for sick animals for a period of three years, and now every county in this State has its crowd of registered veterinarians, utterly innocent of all knowledge that goes to make up the armamentarium of the comparative pathologist, but nevertheless duly licensed to poison, maim, and slay the valuable flocks and herds of the Empire State. A few days ago a gentleman whose horse had his hoof wrenched off in crossing a railroad track was told by the superintendent of the road that he should have applied to him and he would have sent him to the best veterinarian in New York. The practitioner so designated by the superintendent turned out to be one of those registered veterinary surgeons who had graduated from the stable, and by act of the Legislature had been endowed with all the rights and immunities that pertain to the comparative pathologist. The gentleman, however, knew better and saved his horse.

If the action of the Legislature and of the railroad magnates is to be taken as a proper gauge of public

opinion, it is not surprising that New York has done next to nothing, as a State, for the education of the veterinary physician and sanitarian. Such education has been left to private enterprise, and as a matter of course it must be restricted by financial considerations, and the length and thoroughness of the course of study must remain a consideration secondary to the resultant income. It is useless to deny that veterinary education has suffered seriously from this cause, so that the possession of a diploma of one of the schools is not necessarily a guarantee that the owner is a desirably educated man. He has received some training, however, in the fundamental principles of comparative disease and medicine, and if his preliminary education is such as to permit it, and if he is sufficiently industrious, he can carry on his education and make himself an accomplished man.

In Europe, with a system of veterinary schools equipped and controlled by government, they do better. The matriculant must be a B.S. or B.L., or he must hold a first-class professional certificate from a gymnasium, and must thereafter pursue a course of study for four entire years before he can present himself for the final examination for a degree. The records show that even then not more than one-third secure the coveted diploma, and the remainder have to take a fifth or even a sixth year before that desired goal is reached.

If America could have similar government colleges we would be enabled to secure veterinary sanitary officials of the high quality required. In the absence of government schools, something should be done by some of our wealthy universities; but even with them we see as yet hardly the first faint ray of recognition of this great need of the country. Each institution earnestly competes with the others in establishing rival schools of classics, of the general sciences, of philosophy, and many in developing colleges of economics, of law, of agriculture, of architecture, of engineering, of mechanics, of medicine even; but this one subject, which lies at the foundation of all sanitary control of our meats and dairy products, of the preservation and soundness of $2,000,000,000 worth of live stock destined for human consumption, the pathology of our great animal industry, which is essential to the permanent fertility of our soil, is persistently ignored. The University of Pennsylvania and Harvard University have now made a beginning, and we may hope to see a better recognition of this subject in the future.

Of our 43,400,000 cattle, it is estimated that 3 per cent. are tuberculous, while the ratio in dairy cows rises much higher. If, however, we count only 2 per cent. on our 95,200,000 cattle and swine, we have in round numbers 2,000,000 domestic animals daily exposing man and beast to this terrible contagion, and we have a large proportion of these yearly sold from the butchers' stalls as human food. Though we ignore all the other animal diseases communicable to man and confine our attention to this alone, we may well ask, in the light of our sanitary knowledge of to-day, Is it less than criminal to neglect this source of danger, so manifest and so preventable, or to delay educating men for this sanitary service?

The education of efficient men is, however, not enough. Arrangements must be made whereby these men will be enabled to perform their work with system and thoroughness. Our perfunctory plan of inspecting the carcass in the butcher's stall is utterly insufficient. Some contagions that render the meat deadly may at given stages of the disease show to the unaided eye little or nothing abnormal on inspection of the dressed carcass. Splenic apoplexy is a notorious example of this. It follows that the subject must be made to pass the scrutiny of the skilled eye before death and during slaughtering, and that instruments and methods of precision must be called into requisition whenever they may be needed. Such inspection, however, often becomes practically impossible in the private slaughter-house, where the proprietor can control the opening and closing of the doors, the hours of slaughter, the disposal of the products, etc. To secure a satisfactory inspection the abattoir must be a public municipal institution, under strict regulations, and in which all butchers may hire at low rates the facilities necessary for slaughtering and utilizing the products. Apart altogether from the sanitary inspection of meats, this has been generally found to be the most economical, cleanly, inoffensive, and in every way most desirable method; when, therefore, it is also the only method that can insure that the inspection shall be satisfactory it may be held imperative on every city to adopt it. The advantages of one central abattoir appear to have been first realized by a guild of Roman butchers in the days of the ancient empire, but the true municipal abattoir, owned and controlled by the city, we owe to the first Napoleon, who projected those of Paris in the later years of his reign, showing a wise example, which has since been followed by nearly all of the great cities of Europe. The concentration of the work of slaughtering has been attempted in Boston, Philadelphia, and New Orleans, and to a lesser extent in New York, but in nearly every case the ownership has been vested in a private corporation, so that the greatest benefits to the butcher and the public have failed of realization. To give an example of the economy of municipal ownership, the Edinburgh abattoir rents a slaughtering booth, pen, and yard, with all facilities for the utilization of the products, for $40 a year. To the butcher, therefore, it is a real economy, and this object must never be lost sight of in sanitary administration. The community has a right to protect its health by the control of slaughter-houses and the rigid scrutiny of all sources of its meat-supplies; but if in so doing it imposes any undue or unnecessary burden on the honorable butcher, it will only serve to arouse opposition and defeat its own ends. Hence the granting of a charter to any company to erect and maintain an exclusive abattoir is, in my opinion, a most unwise procedure. A public building, owned by the city, controlled by the health board, and conducted on principles specially favorable to the butcher, is the ideal provision, and such an establishment faithfully administered must soon establish its claim to permanence.

As regards the dressed-meat trade, it is manifest that as yet the same strict inspection cannot be applied. It is to be hoped, however, that ere long our cities will be supplied with carcasses stamped with a certificate of soundness, as is now furnished with the meat shipped to Europe, and that the authorities may be able to obtain the assurance of the thoroughness and reliability of such

inspections, whether conducted by government or municipal agents.

Like all reforms, this sanitary inspection of meats and meat-sources will be opposed on the ground that what was good enough for our fathers can be safely borne with. Such an argument, however, proves too much. Could Buffalo maintain her prosperity if the lakes were cleared of all steamers and the traffic once more remanded to sailing craft? Could her business be conducted in the absence of telegraphs, telephones, gas, and electric lighting systems? Could she safely abolish her sewage system or her steam fire-engines? Would it be less than criminal to go back even to untrapped or unventilated sewers? Could the modern surgeon be tolerated if he ignored alike anesthetics and aseptic operations?

Every age has its own status of knowledge, and such knowledge entails a corresponding measure of responsibility. What was an advanced position for our great grandparents would be a reprehensibly antiquated and effete measure in our own day, clogging the wheels of progress and dooming a community or nation to decadence. It is true to-day as in the days of Isaiah, "The nation and people that will not serve the Lord shall perish, yea, that people shall be utterly wasted" (Isa. lxii, 12). With our fuller knowledge of the laws of God's universe, we have a greater trust imposed upon us, and unless we recognize these laws and harmonize ourselves with them in every sphere of human activity we shall fail of our stewardship and lag behind in the general progress. There is a profound truth in the Socratic aphorism "Vice is ignorance; virtue is knowledge." We can modernize it by saying, "To ignore the knowledge of to-day is vicious; to avail of it and practise it is virtuous." Whenever we step aside from a utilization of all available knowledge and skill for the advancement of the material prosperity of the people and the general sanitation we become recreant to our trust, and no consideration of petty economy, of party success, or of national indebtedness to an unfit candidate can remove our action from the category of the vicious and destructive. In regard to the main subject before us—the inspection of animals and meats—we have the highest moral as well as material reasons for securing skilled and honest officials. The movement is destined to conserve the numbers and health of our live stock, without which the native fertility of our soil must steadily decline, and it is destined to protect that most sacred of all trusts, the health and lives of our people, and in consequence the power and prosperity of the nation.

CLINICAL MEMORANDA.

REPORT OF A CASE OF MEDIASTINAL TUMOR, WITH SPECIMEN.[1]

BY NATHAN JACOBSON, M.D.,
PROFESSOR OF CLINICAL SURGERY AND LARYNGOLOGY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

MR. C., a civil engineer, fifty-six years old, had been under my professional care at various times for ten years for slight ailments. His father had died at the age of eighty-six of carcinoma, of the face; his mother at eighty, of apoplexy, having for five years prior to her death exhibited the usual cerebral disturbances incident to atheromatous vascular degeneration. The patient was of an exceedingly nervous temperament, and had been in the service during the Rebellion.

Early in the summer of 1890 he felt unusually enfeebled, and went into the mountains of Pennsylvania to recuperate. He returned in July, 1890, and while engaged in some professional work, on the 28th of the month, he was seized with vertigo and was obliged to go home. Being called, I found his face congested, the vessels of the head and neck greatly engorged; the latter were so distended that the normal contour of the neck was entirely lost. The voice was of a piping character; vertigo persisted; the pulse was somewhat irregular, but soft and not disturbed as to frequency. Recognizing the presence of cerebral congestion due to some obstructive trouble, I prescribed Rochelle salts. For the succeeding four days he was confined to his room, when the vertigo disappeared and the congestion of the head was materially improved. The veins of the neck, and particularly those of the right side, however, remained engorged.

Within a week the clinical picture gradually changed, and venous engorgement manifested itself in the left arm. The swelling slowly extended from the axilla to the hand. By the 10th of August, 1890, the hand and forearm were considerably enlarged. The surface veins of the chest had increased in size, and could readily be seen making a vast network. Change of position, keeping the hand elevated, while the patient was in a recumbent posture, did not in any way affect the size of the left upper extremity. The chest and abdomen were carefully searched for the cause of the obstruction, but physical examination revealed nothing. The opinion was expressed that the existence of a mediastinal tumor would alone account for all the symptoms. The patient denied syphilitic infection; yet, thinking that the obstruction might possibly be due to pressure from a syphiloma, the iodides were administered, beginning with ten-grain doses three times daily; strychnine and digitalis were also prescribed.

The man complained of feeling weak, but was otherwise not materially disturbed. After a few days of confinement at home, he was able to be out and to call upon me at my office. The left upper extremity continued to swell and grow cold. It became somewhat edematous and the edema extended to the chest. He reported that each morning upon arising, his face was quite swollen, but the engorgement disappeared somewhat after being about.

By August 20th the left arm measured 13 inches in circumference, as against 10 for its fellow at a corresponding point; the left forearm 12½, while the right was but 9¾. The swelling and edema of the left side of the chest increased, until the man appeared to have a well developed left mammary gland. At this date the abdominal veins had greatly increased in size, and the area of hepatic dulness was also increased. The right arm now became painful, although not swollen or edematous. The iodides had been steadily increased, so that the dose taken August 20th was thirty grains of the potassium salt three times daily. The urine was color-

[1] Read at the meeting of the Central New York Medical Association, May 31, 1892.

less, of a specific gravity of 1008, alkaline, and contained neither albumin nor other abnormal ingredients. Four days later still, further venous stasis of the left arm was apparent. On the right arm near the elbow an edematous area about two inches in diameter had appeared. The apex-beat of the heart was slightly displaced to the left. The pulse at the right wrist was 105; at the left it could not be made out at all, because of the edematous swelling. The surface veins of the chest and abdomen were rapidly increasing in size. The patient was strongly advised to abandon his work, for up to this time, and even later, he persisted in performing many arduous duties.

During September, 1890, the patient was confined to his house. The swelling and edema of the entire left upper extremity continued, until it seemed as though the skin was stretched to its utmost. Early in the month the right arm began to swell, the swelling extending from the point already mentioned, at the inner side at the elbow, to the forearm and the hand. The veins of the chest and abdomen continued to increase in size.

At the close of the first week of September the man was compelled to sit up constantly, night and day. Any attempt to assume the recumbent posture would produce most distressing dyspnea. He was unable even to sit propped up in bed, but was obliged to occupy a chair, and to secure what sleep he might with his head bent forward and resting upon another chair or upon a table. The respirations grew steadily shallower, and the slightest effort made the man pant. At this time both lower extremities became edematous, the edema reaching to the knees.

On September 25, 1890, the swelling disappeared from both hands and grew less in the forearms and arms. An effusion was present in the right pleural cavity. The area of liver-dulness was increased, so that on October 1, 1890, it extended three inches below the border of the ribs and across the abdomen almost to the free border of the ribs of the left side. The upper border of dulness on the right side was at the level of the third rib, partly from the existence of the pleural effusion. The spleen was also enlarged. Although examination of the heart failed to detect any abnormal murmurs, palpation readily recognized the *fremissement cataire*. The patient's face had grown paler and thinner; his voice was stronger, but his speech was very "choppy." The iodides had been continued in increasing doses, until one hundred and fifty grains were being taken daily. As no improvement, however, followed their administation, they were discontinued, and the medication was reduced to the giving of strychnine in $\frac{1}{10}$ grain doses three times daily. The patient's mind remained clear, and he suffered but little pain.

Early in October, 1890, he decided to go to a water-cure located in Geneva, where at least he might secure absolute rest and receive better personal attention than was possible at home. At this institution the diagnosis of mediastinal tumor was doubted, and the patient was subjected to massage and baths. He sent me word, however, that he was able to breathe better and even to lie down and sleep.

I saw him but once during the spring of 1891, on March 14th, when I found the pleural effusion lessened, and the edema of the extremities greatly improved. The pulse, however, remained above 100, while it was very feeble and intermittent. The veins of the chest continued prominent, while those of the abdomen became simply enormous in size. A limited area of dulness could be made out over the upper portion of the sternum and an inch to the right.

The man was able to walk about during the summer of 1891 and ceased to take medicine. In fact, I failed to see him at all between March and September, and his apparent improvement was so great that his friends even questioned my diagnosis and prognosis. Upon his return to me in September, 1891, I found him substantially free from edema of the upper extremities. On the inner aspect of the arms exquisitely tender and slightly edematous areas persisted. The venous engorgement of the surface, the hepatic and pleural dulness remained, but lessened in extent. Breathing was superficial, and dyspnea, associated with suffocative attacks, was readily provoked. The voice was weak. Inspection of the chest now showed a prominence of the inner extremities of the second and third ribs of the left side and the sternum at this level. This area was exceedingly tender, and the patient could not bear to be percussed at all. Dulness, however, could be mapped out as reaching to the clavicle, and laterally to the mammary line and downward to the fourth rib. At the most prominent portion of the sternal projection a small tumor could be seen and felt. Numerous secondary glandular growths appeared upon the skin, some of them quite large and many even more painful to touch than the sternal growth. The urine was found to be cloudy, pale-yellow, of a specific gravity of 1016, and acid in reaction; earthy phosphates were in excess; no albumin was present; a few uric-acid crystals and pus-corpuscles were found. Aside from the respiratory difficulties the patient had lost all the urgent symptoms that had been so distressing a year before. The edema of the upper extremities never returned. He was able to lie down and occupy his bed at night; he was very feeble, yet walked about slowly with the aid of a cane, and was not again confined to his room until January, 1892, when the dyspnea had become very distressing and persistent.

He was once more compelled to spend his days and nights in a chair, and the barest movement greatly intensified his orthopnea. His face was again congested and apparently fuller, although his body was very much emaciated. The veins of the neck and chest remained engorged, while those of the abdomen were numerous, being almost the size of a man's finger. The tumor steadily crowded the chest forward, the area of dulness increased, and over it tubular breathing could be heard. The heart was irregular and feeble in action, and showed the purring vibration. A pleural effusion was present and the liver-dulness was unreduced. In this condition the patient passed the month of January, 1892, unable to take but a step or two without being distressed for want of air. His mind remained clear. Defecation was exceedingly difficult. His appetite failed.

On about the 10th of February, 1892, with increasing exhaustion and very superficial panting respiration, he became steadily more oblivious to what was transpiring about him. In this exhausted condition he again assumed the recumbent posture. For the nearly two weeks

that elapsed until his death occurred he grew gradually more feeble and died very peacefully.

The autopsy was made on the day after death, in the presence of Drs. Didama and Sears. After section of the costal cartilages it was found impossible to raise the sternum at the point of penetration by the tumor. A portion of the sternum four inches in length and three in width was therefore cut out, the center of which was occupied by a portion of the tumor; this had infiltrated the bone from within and appeared upon its anterior surface as a growth two inches in length by one and a half inches in width and about one-half inch in thickness. The right pleural cavity contained about one quart of fluid. The tumor had so thoroughly infiltrated, and, in fact, become a part of the thoracic organs, that their removal could only be accomplished *en masse*. This being done, it was found that the tumor cemented the chest contents to the sternum by a hard, infiltrating nodular mass, which not only surrounded but literally invaded the venous channels leading to the heart. The trachea was compressed anteriorly and upon the right side, and was itself firmly adherent to the growth. The right bronchus was entirely imbedded. The tumor extended into and, in fact, absolutely through the right lung, separating the upper from the middle lobe by a rounded, projecting mass that extended downward a distance of five inches, encircling the descending aorta, and at its widest part measuring five inches in diameter. Throughout, the tumor presented lobulated outgrowths. Only the lowest portion of the inferior lobe of the right lung exhibited any patent air-cells; the remainder was a solid mass impenetrable to air. Anteriorly the tumor surrounded the arch of the aorta, constricting it and overlapping the upper portion of the base of the heart. Not stopping here, the tumor absolutely invaded the heart itself. A prolongation fully two and one-half inches in length, constricted at its center to such an extent as to be almost cut in two, extended into and almost completely filled the right auricle. Its presence had, no doubt, led to marked distention of the auricle, which was considerably dilated and its walls much attenuated. The growth invaded the heart-structure and was quite firmly adherent to the auricular walls. No secondary growths appeared in the liver. The left lung was free from invasion. The kidneys were normal. Dr. Sears made a microscopic examination of the tumor, and reported the growth to be a small round-celled sarcoma. In some parts the cells were very numerous, the inter-cellular substance slight in amount, and the bloodvessels thin-walled. In other parts the connective tissue was very dense and the bloodvessels more highly organized.

REMARKS.—I do not intend to prolong my report of this case by any extended remarks. I present the specimen, which better than any words makes manifest its most unusual features. I desire simply to emphasize the very rapid and serious manifestations of the disease during its early months. For two months following my first visit, at the close of July, 1890, its active development justified the prediction that death could not be long delayed. Yet, despite the fact that the tumor must have been steadily growing and constantly invading vital structures, as the vessels accommodated themselves to the pressure and collateral circulation carried the blood to the previously obstructed areas, a great respite was granted.

We cannot but marvel at the rare endurance of a heart invaded by a malignant growth that occupied one of its chambers almost to the exclusion of the entering blood-current. Tumors of the mediastinum are rare enough, but in reviewing the literature of the subject I have as yet failed to find one recorded that exhibits an invasion of the heart similar to that here reported.

GUNSHOT WOUND OF THE ABDOMEN DURING PREGNANCY; RECOVERY.

BY C. A. MILNER, M.D.,
OF WYOMING, IOWA.

WHILE Mrs. M., twenty-one years old, in the sixth month of pregnancy, was oiling a 32-caliber revolver, it accidentally went off. The ball struck a steel of her corset, was deflected, and entered the abdominal cavity on a line drawn from the left nipple to the anterior superior spine of the right ilium, three inches from the ensiform cartilage, thence it pursued an upward, backward, and outward course—passing through the skin, superficial fascia, the external and internal obliquus and transversalis muscles, both layers of the peritoneum, the external border of the central tendon of the diaphragm, one inch from the apex of the heart, the pleura, and lung, and became lodged in the lung at the posterior border of the serratus magnus muscle.

I was called five minutes after the accident. The woman, unable to lie down, was sitting on a couch, faint. I gave her a dram of whiskey in hot water. In a few minutes she could lie down on the couch. She immediately began to expectorate bloody, frothy mucus, and was in great pain. I gave morphine hypodermatically, and she could then lie on her side. There was some shock. The pulse was quick and strong. The woman was remarkably cool and self-possessed, and did not seem to fear the outcome of the accident. There was very little hemorrhage from the external wound, but more through the bronchial tubes.

I dressed the external wound antiseptically. After picking away foreign particles I washed the wound thoroughly with a solution of boric acid, dusted boric acid over the surface, and applied borated gauze and adhesive straps. The left half of the chest was strapped, to secure as complete immobility as possible. I directed the patient to lie upon the right side, so as to secure drainage through the bronchial tubes and the external wound. The chest was raised higher than the hips. I ordered some whiskey punch. The cough was very distressing. For its relief I gave a mixture containing syrup of squills, morphine, glycerin, chloroform, and hydrocyanic acid.

The pulse was 90, the temperature 100°, the respiration 25. The breathing was of superior costal type, and shallow. The bowels had acted on the morning of the accident. There was no vomiting. The stomach was empty. There was very little nervous disturbance. The woman was cheerful. At 9 P.M. I prescribed syrup of ipecacuanha and opium. The patient slept fairly well. I saw her every two hours on the following days. At 12 midnight the temperature was 100.5° F. At 2 A.M. the patient coughed up some bloody, tenacious sputa. Expectoration was difficult on account of pain. The pulse

was 100, the temperature 100.5° F. Headache was complained of. I administered a powder of acetanilide and caffein citrate, which afforded relief. The woman took some nourishment, including milk toast and a poached egg. After eating, I gave her pepsin and dilute hydrochloric acid to lessen peristalsis and aid digestion. Before eating, I gave her a capsule of iron chloride and glycerin. In case of traumatism and in pregnancy the white blood-corpuscles are increased, the red ones diminished in number, and the proportion of hemoglobin is diminished. Iron is therefore indicated. A greater amount of sodium chloride was added to the food than usual. Sodium chloride exerts a beneficial influence in cases of penetrating wounds of the thorax. Fetal movements were first felt during the day. The respirations were 28 in the minute. Diaphragmatic breathing was almost entirely wanting on the left side. The urine was high-colored and loaded with urates, uric acid, and phosphates; the chlorides were diminished.

There was no flatulence. The patient was absolutely quiet. At 9 P.M. the temperature was 100.8°, the pulse 100, of high tension, hard and wiry. Symptoms of localized peritonitis appeared. I ordered hot applications to the epigastrium, and gave powders of ipecacuanha and opium. There was no vomiting. The heart-sounds were intensified. I gave acetanilide, and the pulse became softer. During the night the cough-mixture was repeated twice. On the following morning the sputum was muco-sanguineous; the temperature was 99.8°. The patient still lay on the right side. She took egg-nog and toast, and passed a good day. I dressed the external wound. There was no suppuration, but evidence of occlusion of the external wound, which I dusted with boric acid and covered with borated gauze. At 11 P.M. there was great thirst, and the temperature was rising. There was more cough, and the breathing was panting and accelerated to 32 per minute. The face was flushed; the temperature was 101.5°. Evidences of pleuro-pneumonia appeared. By means of acetanilide and caffein citrate, I kept the temperature within 100° F. On the following day there was some sweating. The fever was less. The urine was scanty and high-colored. The appetite was good. The patient took milk and lime-water. At 5 A.M. I gave potassium acetate. At 11 A.M. the urine was increased in quantity. The proportion of potassium salts and chlorides was increased. Thirst was relieved by small pieces of ice in mouth. At 9 P.M. the temperature was 101° F.; cough had increased; the pulse was 100, bounding and full. The woman got some sleep during the day. The urine contained no albumin; its specific gravity was 1030. There was no pleuritic effusion. Some crepitation was to be heard. The respirations were 32, panting. Bronchophony was evident. Percussion revealed no abnormality. On auscultation, dry, crackling, and crepitant râles were heard at the end of inspiration. The patient did not sleep well that night.

On the morning of the next day the pulse was 96, the temperature 100.6°. The sputum was rusty. The woman took nourishment. There was slight dulness on percussion over the left lung. At 12 o'clock noon the woman took nourishment and some castor oil. There was slight dulness over the left lung, with increased vocal resonance in a localized area. The breathing was bronchial, 28 times to the minute. Moist râles and some gurgling were heard, but no bronchophony. The sputum was rusty and muco-purulent. No pneumonia-cocci were found, and but few pus-cells. In the afternoon the expectoration was easier and contained some broken-down tissue. On the next day the temperature was 100°, the patient slept better, and cough required less effort. A day later the temperature was 99.6°. The patient took milk and eggs. The sputum was muco-purulent. The external wound showed signs of cicatrization. The greater part of the drainage was evidently taking place through the lung. Strong coffee was ordered as a beverage to stimulate the arterial system, especially the uterine arterial system, and to lessen the amount of blood at the seat of injury.

The pregnancy seemed to exert a favorable influence on the outcome. The cutaneous circulation was good. Perspiration was free. The temperature was 99°, the respiration was 24; inspiration was deeper. On the next day the temperature was 98.8°, the pulse 80. Backache was relieved by massage. In the evening the temperature was 99°. Mucous râles and cavernous sounds were heard over the course of the bullet. The sputa was light in color, the breathing deeper—24 times per minute—and without pain. The affected side could now be moved. The movements of the fetus were again perceived. I could locate the ball, but at no time could detect amphoric breathing or gurgling over the site. There was perfect drainage through the lungs; consequently there was no indication for making an incision and extracting the ball, with the risks of infection. The ball finally became encysted. It caused no pain or inconvenience whatever. On the following day the temperature was 98.8° F., with very little cough. The appetite was good. The external wound was cicatrized. There was no pain on inspiration. The urine contained an increased amount of chlorides. The phosphates, uric acid, and kreatin were diminished. The evening temperature was 98.6°. On the next day the temperature was 98.4°. The patient was now convalescent, and sat up. Sixteen weeks later she gave birth to a perfectly formed and healthy female child, weighing seven pounds.

A CASE OF IDIOPATHIC PHLEBITIS.

BY JOHN O. BROWN, M.D.,
OF MINNEWAUKAN, N. D.

ON February 5, 1892, Mr. H., a Swede, seventy-two years old, presented himself, stating that about two weeks previously he had noticed a painful spot on the ulnar side of the left wrist, near the median line, at the site of which a small ulcer formed. A week later the anterior ulnar and basilic veins became painful and swollen so as to resemble thick cords beneath the skin, reaching from the ulcer at the wrist to the axilla. The man had had no chill, and the pain was not sufficient to prevent him enjoying sound and refreshing sleep. He appeared hale and hearty, and there was no indication of the absorption of pus. There was no history of syphilis.

Upon examining the arm I found considerable edema; the skin over the affected veins was of a coppery-red color, looking as if a broad stripe had been painted from the axilla to the wrist. On the forearm there was a sinus

following the course of the affected veins for a distance of about five inches, and discharging pus and serum at the ulcer on the wrist. Above this sinus were several swellings in the course of the affected veins. These swellings were directly over the inflamed veins, and fluctuation could be detected in them.

The case was diagnosticated as one of idiopathic phlebitis, by extension involving the surrounding tissues.

It was directed that the arm be carried in a sling during the day, and at night to be slightly elevated on a pillow at the side. Tincture of the chloride of iron was prescribed in fifteen-drop doses, to be taken in water before each meal. A generous diet was also advised. Each swelling along the course of the affected veins was freely incised, and the sinus was opened so as to allow thorough drainage. Wherever there was any pus I injected hydrogen dioxide (fifteen-volume solution). The sinus was thoroughly irrigated with the same solution. The irrigation was repeated daily for over a week, when I had the satisfaction of seeing the small abscesses heal. The sinus remained, but in no worse condition. The edema of the surrounding tissues had subsided, and there was no pain along the affected veins. The veins were not so thick as they had been. The coppery-red stripe over them gradually narrowed until it was obliterated in some places. The patient's appetite was good throughout his illness. He was given a solution of corrosive sublimate (1 : 2000) and a syringe, and instructed how to daily irrigate the sinus at home.

He returned once a week to have me look at his arm, and, as at the end of a month the sinus did not seem disposed to heal, I bandaged the arm to support the circulation. This had the desired effect, and the sinus soon healed.

According to Virchow, idiopathic phlebitis is a comparatively rare affection. Hamilton says that it may result from exposure to cold. Wyeth, in his recent admirable work on *Surgery*, says that, from whatever cause it may proceed, it usually affects the veins of the lower extremities.

Taking into consideration the age of the patient—seventy-two years—it seems to me that the cause of the condition in the case here reported lay in senile changes in the enlarged veins, in conjunction with exposure to cold while the patient was engaged in his accustomed light farm-duties in the winter-time. The sluggishness of the flow through the enlarged veins at the wrist resulted in stasis of the blood, which being acted upon by intense cold, probably became coagulated so as to form a thrombus. This thrombus, acting as a foreign body, gave rise to inflammation in the tissues surrounding the vein at a point exposed to the most movement—*i. e.*, the wrist. Here was the initial lesion, and from this the inflammation spread along the vein.

On the first of May the affected veins still felt like heavy cords beneath the skin, and I believe that the function of both veins has been obliterated throughout the extent that was inflamed. Had the inflammation extended only a short distance along the arm instead of into the axilla, I would have considered the wisdom of exsecting the whole of the inflamed portion; but, as there was no means of deciding how close to the heart the inflammation had extended, the operation would have been of doubtful propriety.

MEDICAL PROGRESS.

A New Osteoplastic Procedure in the Treatment of Spina Bifida.—BOBROFF (*Centralbl. für Chirurgie*, 1892, No. 22, p. 465) has reported the case of a boy eight years old, with a sacral myelo-meningocele, in which he employed a new procedure. The sac had a diameter of almost two inches at its base and a height of more than two inches and a half. The sac could be emptied by pressure, which caused pain and vertigo. Since birth there had been rectal and vesical incontinence. The skin-covering was removed between two semilunar flaps. Some nerve-fibers of the cauda and the termination of the cord were freed from the inner surface of the sac and deposited in the sacral canal. The lining membrane of the sac was now removed. From the adjacent crest of the ilium a segment of bone, large enough to close the defect in the sacrum, was removed, but permitted to remain adherent to its nutrient attachments, the periosteal surface presenting posteriorly. For the sake of security, two bone-sutures were introduced. The wound was then closed and provision made for drainage inferiorly. The boy was made to assume the prone position. For a few days there was slight elevation of temperature and considerable discharge. The drainage-tube was removed at the expiration of two days. In the course of two months the transplated segment of bone had become quite consolidated. The sphincters were at first stimulated by faradism and then by galvanism. At the expiration of five months considerable improvement had taken place.

Steel in the Iris for Twenty-seven Years.—As a sequel to the report of a case in THE MEDICAL NEWS of October 10, 1891, p. 428, in which a bit of steel had been lodged in the iris for twenty-seven years, KEIPER (*Indiana Medical Journal*, July, 1892, p. 8) records the further history. The man presented himself with an attack of intense inflammation of the affected eye. The employment of leeches, atropine, and hot fomentations not proving sufficient, an attempt was made to remove the foreign body by means of an electro-magnet. As there appeared to be danger of bringing away the adherent iris with the bit of steel and of dislocating the lens, an iris-forceps was employed, and the piece carefully removed by teasing. The fragment of steel was $\frac{3}{16}$ of an inch long and quite irregular. The ultimate result was eminently satisfactory.

Reinforcement of the Knee-jerk.—ROSENBACH (*Centralbl. f. Nervenheilk. u. Psychiatrie*, July, 1892, p. 336), recommends that in cases in which the knee-jerk cannot be elicited by simply striking the patellar tendon or by striking the tendon while the upper extremities are engaged in some voluntary muscular movement, the patient be directed to rapidly read aloud while the tendon is struck. An absence of response is conclusive. By the act of reading the attention is so engrossed that the influence of cerebral inhibition and of voluntary muscular effort is removed.

The Bacillus of Chancroid.—At a meeting of the French Society of Dermatology, QUINQUAUD (*La Médecine Moderne*, 1892, No. 28, p. 457) reported that in a number

of cases of chancroid he had found the bacillus described by Unna. The same organism was always found in large numbers. It was rod-shaped, with rounded extremities, and usually arranged in chains. It was present in the depth of the tissues, especially in the lymphatic and intercellular spaces, but never within the cells themselves. Its staining was difficult, and was best secured by a carbolized blue.

A Delicate Reaction for the Presence of Albumin in the Urine.—SPIEGLER (*Internationale klin. Rundschau*, 1892, No. 27, p. 1112) recommends the following test-solution for the detection of the presence of albumin in urine: Tartaric acid, 10 grains; mercuric chloride, 20 grains; white sugar, 50 grains; water 1 ounce. The urine is filtered, slightly acidulated with acetic acid, and carefully made to overlay the test-solution in a test-tube. If the urine contain albumin, a sharply-defined white ring appears at the line of contact. Peptone gives no response, while propeptone does.

Death During Pregnancy Caused by a Swallowed Spoon.—LIHOTZKY (*Centralbl. f. Gynäkol.*, 1892, No. 26, p. 489) has reported the case of a woman, thirty-three years old, in whom a rapidly fatal peritonitis developed in the eighth month of pregnancy. At the autopsy, the duodenum was found perforated by a silver spoon that had been swallowed two and a half years previously, although no symptoms had been present in the interim, and the event had almost been forgotten.

Appendicitis.—POTHERAT (*Rev. Gen. de Clin. et de Thérap.*, 1892, No. 28, p. 440) expresses the opinion that surgical interference for the relief of appendicitis is indicated in case of perforation, however small the chance of success appears to be; in case of suppuration in the right iliac fossa; in case of recurrent paroxysms that increase in frequency and intensity. The dangers of operation are not greater than the risks of suppuration or perforation.

THERAPEUTIC NOTES.

The Cure of Tetanus with the Antitoxin Obtained from the Serum of an Immune Animal.—CASALI (*Centralblatt f. Bakteriol. u. Parasitenk.*, xii, 2 u. 3, p. 56) has reported the case of a woman, twenty-two years old, who, seven days after having received a lacerated wound of the right foot, and walking a considerable distance over damp ground with unprotected feet, presented manifestations of developing tetanus. For a week, under ordinary treatment, the symptoms progressively increased in intensity. Specific treatment was now proposed and assented to. Tetanus-bacilli were found in the pus from the wound on the foot. Six injections of the antitoxin prepared from the blood of a dog immune to tetanus were made at intervals of twelve hours; the first five contained 25 centigrams, and the sixth 15 centigrams. Improvement soon set in, and was progressive to perfect recovery.

The Toxicity of Exalgin.—BROADBENT (*Lancet*, No. 3596, p. 256) has reported the case of a man, twenty-six years old, who presented toxic symptoms after the ingestion of twelve grains of exalgin for the relief of neuralgia. Four grains were taken in the evening, with relief from the pain, though giddiness was felt. The pain returning early on the following morning, twelve grains more were taken. The man immediately became dazed, fell to the floor, and remained unconscious for half an hour, during which he frothed at the mouth. The pulse was feeble and slow, while epigastric pain and noises in the head were complained of. The subcutaneous injection of $\frac{1}{10}$ grain of apomorphine was followed by thorough evacuation of the stomach. Subsequently, $\frac{1}{500}$ grain of strophanthin and ten minims of ether were administered, and the man slowly rallied.

Methyl violet in the Treatment of Diphtheria.—JAENICKE (*Therapeutische Monatshefte*, 1892, H. 7, p. 340) has employed a saturated solution of methyl-violet in the treatment of diphtheria. The application is made by means of a pledget of cotton, and is repeated in the course of from two to five hours, as soon as the discoloration has disappeared. Methyl-violet exerts an inhibitory influence upon the development of the diphtheria-bacilli, and possesses the advantage of being relatively non-toxic.

HOERING (*Memorabilien*, 1892, H. 6, p. 327) reports fifteen cases of diphtheria in the treatment of which he employed topical applications of a three per cent. solution of methyl-violet, with most satisfactory results. Two of the cases that came under observation in a condition of profound intoxication died.

Pheno-salyl: an Antiseptic Mixture.—The following combination is recommended as an active and soluble antiseptic:

℞.—Acid. carbolic.	. . . .	ʒjss.
Acid. salicylic.	. . . .	gr. x.
Acid. lactic.	. . . .	gr. xx.
Menthol.	. . . . .	gr. j.—M.

The three acids are warmed to liquefaction, and the menthol is added. The mixture is to be diluted as required.—*Annales de l'Institut Pasteur; Journ. de Méd. et de Chir. prat.*

Potassium Bichromate as an Expectorant.—Based upon an extended experience, HUNT (*Brooklyn Medical Journal*, 1892, No. 8, p. 516) recommends the employment of potassium bichromate as an expectorant, especially in catarrhal conditions of the respiratory mucous membrane. The remedy is best administered by rubbing up one grain with nine grains of sugar of milk, and adding the desired number of teaspoonfuls of water. A child a year old may be given from gr. $\frac{1}{30}$ to gr. $\frac{1}{20}$, at intervals at first of ten or fifteen minutes, but subsequently less frequently.

Intra-uterine Injections of Glycerin to Stimulate Contractions of the Uterus.—PELZER (*Archiv für Gynäkologie*, Bd. xlii, H. 2, p. 220) reports a number of cases in which intra-uterine injections of glycerin were employed to stimulate contractions of the uterus, both in premature labor and in labor at term. From an ounce and a half to three ounces of glycerin were, by means of a syringe and a catheter, introduced between the membranes and the walls of the uterus as high up as possible, without rupture of the membranes.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, Including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, AUGUST 27, 1892.

AS TO A FOUR YEARS' COURSE.

AN esteemed correspondent calls our attention to a number of facts that he deems militate against the position taken by THE NEWS in regard to the compulsory four years' course. At Ann Arbor, which was the first college to adopt the four years' course, as well as at Harvard and Columbia, the term is already nine months, and at the University of Pennsylvania the term is seven months, and will be lengthened; yet at all of these institutions a course of three years is found to be too short in which to teach all that modern medicine demands, and what is taught overworks the student.

The University of Pennsylvania, like Harvard, has adopted a rule admitting to the second year's class men with a college degree who are qualified in general biology, human and comparative anatomy (including embryology and histology), botany, chemistry, and physics; such students to make up materia medica and pharmacy. Exception is likewise taken to our criticism of chemical teaching in so far as it applies to certain schools.

We did not mention the facts cited by our correspondent, because we were dealing with a general question and cited special schools but by way of illustration, not with any view to special criticism.

That the colleges named have adopted the nine-months' term proves that we are correct in our position that all colleges should adopt it.

That advanced standing is granted to qualified students confirms our position that the so-called first year in our four-year courses is virtually a preparatory course, and should be named and organized accordingly. Even PROVOST PEPPER, than whom none has given greater proof of devotion to the higher education, and whose courage is as undoubted as his opportunities for observation are unexcelled, felt constrained in his address at Boston to question the practical wisdom of lengthening the medical course to four years, at the same time that the requirements for admission were increased. And has not PRESIDENT ELIOT, in advocating the curtailment of the course in arts to three years, virtually expressed the same fear?

But it is in the preliminary training, rather than in the teaching in our medical schools, that America in now at fault.

Thus, great as is the ability and merit of certain teachers, and advanced as are the problems with which, *e. g.*, PROFESSOR VAUGHAN deals, and doubtless teaches to the chosen few that can comprehend them, the broad fact remains that the general course at medical colleges cannot deal with that advanced biochemistry that the time demands, simply because the students have not done the preliminary work necessary to its understanding.

The place to begin to reform medical education is at the foundation, not at the roof. We are but confirmed in our opinion that the proper plan is to change the standard of entrance-qualification by increasing the breadth of the preliminary education demanded, thus making that preliminay standard a scientific rather than a merely literary one; to give two terms of nine months each of recitations and laboratory-work, with a modicum of clinical lectures, and a third term of laboratory and hospital work in sections, with clinical lectures for the class as a whole. If it were practicable—as we admit it is not—the degree given for this should be Bachelor of Medicine; and the doctorate should be won by additional work in investigation, in literature, or in practice.

This plan would, of course, require a largely increased teaching staff, while the number of students would be diminished; it might necessitate the consolidation of rival schools here and there; and might cause the death of other schools; none of which events would be a public misfortune.

THE TELEOLOGY OF SUNBURN AND TAN.

The extreme heat of the summer through which we are now passing has called forth from all sides demands for preparations for the prevention of sunburn and tan. Divers unguents and lotions have been recommended, but with these we shall not deal, choosing rather to call attention briefly to the pathology and to the possible teleology of the affections.

When delicate faces and arms are exposed to sunlight there develops a hyperemia more or less acute, and in some even a severe dermatitis, with induration, heat, redness, and edema. If the burning be intense, desquamation follows, and later there is an increased deposition of pigment in the deep portion of the rete Malpighii.

The pathologic process is probably to be explained by a necrosis of cells, resulting from the action of the heat and light. Such a cell-death would be accompanied by the setting free of certain substances, some of which are positively chemotactic. Hence may result the ordinary phenomena of inflammation, and, following the subsidence of the inflammatory process, pigment-making cells manufacture quantities of dark pigment-granules, and store them them up in connective-tissue cells that lie between the columnar epithelial cells that rest upon the basement membrane separating the epidermis from the cutis vera. When the burning takes place more slowly such a deposition of pigment may result without the occurrence of acute inflammation.

From a teleologic standpoint some new light has been thrown upon this matter of pigment-formation by the ingenious speculations of Buchner ("Ueber die Schutzstoffe des Serums," *Berliner klin. Wochenschrift*, 1892, No. 19) in a recent article on the protective substances of the blood-serum. The fresh blood-serum of man and animals, besides possessing the power of quickly killing living bacteria (Groiiman, Nuttall), and of destroying the red blood-corpuscles of an animal of a different species (Landois), is by some believed, under certain circumstances, to exert an antitoxic action upon the poisons produced by the microörganisms of a given disease.

Buchner has shown that these properties of the serum—germ-killing, globulicidal and antitoxic—lie in certain obscure chemical bodies of extreme instability. Warming the serum for half an hour at a temperature of 55° C. destroys them, as does also the action of diffuse daylight, and more quickly still the rays of direct sunlight.

While, therefore, light is an important element in the growth and development of most animals and plants, yet light in the wrong place would probably have a deleterious influence, and it seems as if it were by no accident that certain organs have been buried in the interior of the body and covered with a protecting integument.

In the South the protective powers of the skin are increased by the presence of intense natural pigment-deposits, and we are tempted to regard the sunburn and tan of spring and summer as an approach to such a protective pigment-deposition, the pigment in these cases probably having its origin in disintegrated hemoglobin.

SELECTION.

HIGHER MEDICAL EDUCATION.

If we are to have a continous advance in the standard for admission to our colleges, and then to exact a prolonged course of medical study, it will break the backs of the best schools. We cannot alter the social habits of a nation to make them conform to our notions of what the standard of teaching in this or that department shall be; we cannot reconcile any large proportion of our fellow-citizens to seeing their sons or their wards delay, until the age of twenty-five, twenty-six, and twenty-seven years, entrance upon practical life in order that they may win a B.A., or a B.S., and then get their M.D. in a four-year medical school. I am as convinced, as of anything, that it is absolutely necessary for the medical schools that are going to exact a four-years' course to make provision for obtaining the double degree in less than eight years. That this must be accomplished in some way I feel absolutely certain.

Do not let us handicap medical education too heavily. Dot not let us ask our Faculties to turn out thoroughly trained men, trained at the bedside, giving that clinical instruction which alone renders a man fit to take charge of suffering humanity, and deny them the laboratory facilities which are necessary. Do not ask them to set a high standard of admission; a higher standard of entrance examinations, to pass a second examination before a State Board of Examiners, and put the whole of this on at the same time that we appeal to them to take a college course for four full years. If you provide your medical school with endowment, you will accomplish this for a limited number of the highest grade of students, but you will shut out from your doors those whom I would gladly see here, not to swell your ranks, but because I hold that no matter where the doctor goes to practise his calling—and the more remote the point, the further from the centers of education, the further from the chances of professional assistance, the more essential does his thorough, practical equipment become—you will shut out from your doors hundreds of those who are

the very men we would be glad to see here. You need more fellowships, more scholarships, in your medical department to-day, upon its advanced scale of medical instruction, than you need in any other department of the university. You must have endowment for your hospital. You must have endowment for your professors' chairs.—Dr. Pepper, *Boston Medical and Surgical Journal.*

REVIEWS.

A Text-book of the Practice of Medicine for the Use of Students and Practitioners. By R. C. M. Page, M.D., Professor of General Medicine and Diseases of the Chest in the New York Polyclinic, etc. Pp. 568. New York: Wm. Wood & Co., 1892.

The chief objects of this book, as stated in the preface, are to facilitate clinical instruction and to enable both physician and student to obtain in brief the most practical as well as the most scientific view of the various subjects considered in a work on medicine.

Accordingly, we find the articles touching only on the chief points in pathologic anatomy and etiology, for instance, while the treatment outlined is fully in accord with recent advances; not only are drugs mentioned, but, in many instances, both the prescription and dose are given.

We can hardly endorse the statement "that many persons addicted to the opium-habit overcome it by sheer force of will-power." Such has not been our experience, nor does it coincide with the recorded testimony of most clinical observers.

The reviewer's notice has often been directed to a frequent error that occurs not only in medical books and periodicals, but also on druggists' labels, etc., of using *spirits* for *spirit;* for instance, sweet *spirits* of niter, aromatic *spirits* of ammonia. This error is of frequent occurrence throughout the pages of the present volume.

In the article on "Malarial Fevers" no mention is made of the diagnostic value of the presence of the blood-parasites that have been studied and described by Laveran, Marchiafava and Celli, Golgi, Osler, Dock, and others.

The temperature in typhoid fever, when it rises above 103° F., is directed to be treated in one of two ways: (1) by the internal administration of drugs, and (2) by the application of cold by some means.

Among the drugs mentioned, the author prefers, in the order named, antifebrin, phenacetin, antipyrin, and quinine. In our experience the employment of depressing agents, such as the first three drugs, should be reserved for use only after a fair trial of well-known remedies, such as quinine, cold or tepid sponging, etc. If any of the coal-tar products is used, antipyrin is, we believe, the least dangerous and the most successful.

In conclusion, we think that the present volume will be found acceptable to the busy practitioner as a work for easy and ready reference to obtain a practical view of the latest treatment of disease; but we cannot advise the undergraduate to procure it for use as a text-book; for we are among those who believe that the foundation of a student's knowledge of medicine should be as thorough as possible—especially in the symptomatology, etiology, pathology, and diagnosis of disease—on which points Dr. Page's book, as it were, is a mere compend. This fact is stated, not to the discredit of the work, for it is an excellent medical treatise, and well worthy of perusal by the practitioner or post-graduate student.

Cerebral Meningitis. By Martin W. Barr, M.D., Resident Physician in the Pennsylvania Training School for Feeble-minded Children, etc. Pp. 93. Detroit: George S. Davis, 1892.

While the crudities of this little brochure might perhaps have been overlooked in a graduation-thesis, they cannot escape criticism, formally presented to the profession as they are. The work gives evidence of the expenditure of a good deal of literary research and is deserving of a much better presentation than it has received. There is little evidence of analysis, though there is considerable citation of authority. When it is stated that the arachnoid "is never the seat of inflammation," the question naturally arises as to the authority for so emphatic a negative statement, while there is nothing to remove the doubt as to its accuracy. By a literal translation Morgagni is made to speak of an "exudation of gelatin." In another place, dropsy of the ventricles is quoted as being "caused by inflammation of the meninges or bloodvessels." It must require a refinement of discernment to recognize *internal* cephalalgia. The following remarkable recommendation is made for the treatment of pachymeningitis: "Bromides and narcotics are very useful, given *ad libitum* when necessary, to quiet the cerebral excitement." Elsewhere it is stated that "the most valuable hint in regard to the treatment of hematoma is this: Decide upon your line of treatment and do not change it, except for good and sufficient reasons. Never give up hope until the patient is absolutely dead." Masturbation is suggested as a possible cause of meningitis. The tautology of *traumatic injury* finds repetition. The adjective verticalar is manufactured to indicate the convexity. The synonyms of the various conditions discussed are presented in seven languages. We fear that Dr. Barr has brought forth a premature production the vitality of which is exceedingly doubtful.

CORRESPONDENCE.

THE HYGIENE OF MENSTRUATION.

To the Editor of The Medical News,

Sir: In The Medical News of April 23d I have noticed a reference to a paper concerning "Some Results of Withdrawal," by Dr. L. Bolton Bangs, of New York. I am glad to see the pernicious practice condemned. I have had under my care several patients, some of them married people, who have received considerable injury from this procedure. One woman's nervous system was very seriously injured by this unnatural practice of her husband. The habit is much more frequent than we would be led to suppose from the scanty literature on the subject. Many married people make a practice of the act if, for any reason, connection takes place during the menstrual period, and others, on all occasions.

A reference to the old biblical laws may be interesting in this connection.

We read in the fifteenth chapter of the third book of Moses, called Leviticus, the following laws concerning the menstrual woman:

"19. And if a woman have an issue, and her issue in her flesh be blood, she shall be put apart seven days: and whosoever toucheth her shall be unclean until the even.

"20. And every thing that she lieth upon in her separation shall be unclean: every thing also that she sitteth upon shall be unclean.

"21. And whosoever toucheth her bed shall wash his clothes, and bathe himself in water, and be unclean until the even.

"22. And whosoever toucheth any thing that she sat upon shall wash his clothes, and bathe himself in water, and be unclean until the even.

"23. And if it be on her bed, or on any thing whereon she sitteth, when he toucheth it, he shall be unclean until the even.

"24. And if any man lie with her at all, and her flowers be upon him, he shall be unclean seven days; and all the bed whereon he lieth shall be unclean.

"25. And if a woman have an issue of her blood many days out of the time of her separati on, or if it run beyond the time of her separation; all the days of the issue of her uncleanness shall be as the days of her separation: she shall be unclean.

"26. Every bed whereon she lieth all the days of her issue shall be unto her as the bed of her separation: and whatsoever she sitteth upon shall be unclean, as the uncleanness of her separation.

"27. And whosoever toucheth those things shall be unclean, and shall wash his clothes, and bathe himself in water, and be unclean until the even.

"28. But if she be cleansed of her issue, then she shall number to herself seven days, and after that she shall be clean. . . .

"31. Thus shall ye separate the children of Israel from their uncleanness; that they die not in their uncleanness, when they defile my tabernacle that is among them."

Lieut. Totten and other writers have endeavored to demonstrate that our North American Indians are the remnants of the lost tribes of Israel, and they certainly present powerful arguments to support such a view. Is not the custom prevailing among our Indians of considering the menstruous women "unclean" something more than a mere coincidence? A tradition so powerful and a dread of disobedience so intense, that the isolation of a menstruous women is never broken by the wildest and most lawless of savages, certainly must attract our serious attention.

Among the Anglo-Saxons I think we may safely assert that a menstruating woman can only with some little difficulty conceal the fact of her "sickness." Certainly medical men must often notice the peculiar bearing and the facial appearance, besides the physical symptoms, of a woman menstruating, and very often even the disgusting odor. While to our notice as medical men it frequently comes about that we are informed of men of all stations in life cohabiting with women during menstruation, I think it can be safely asserted that among men of ordinary education, refinement, and good taste, and even among the comparatively poor and ignorant, a menstruous woman is let alone until she is "clean." It seems to me that this custom of isolation is returning. Married women leave the conjugal bed and retire for a few days to some "spare room," and after a complete bath and change of linen, and the use of perfumery and other methods of purification, return to married life again. This is certainly as it should be, and is the opinion of many medical men I have no doubt.

In Germany, at least, we find the regulations concerning the care of menstruating girls well worth imitation in this country. There a girl at such times retires and generally goes to bed, and remains in bed for at least from forty-eight to seventy-two hours, if not longer. It is no shame to be a normal woman in Germany, and the function of menstruation is encouraged and protected, not ignored or interfered with, as it is so often in the United States. It is not the purpose of this communication to write upon the subject of menstruation as it applies to the care of our American patients, but quite enough has been stated to cause any thoughtful physician to repeat the warnings he has undoubtedly given his patients, time and again, to insist upon greater maternal watchfulness in the development of our girls, and to encourage that respect for womanhood and motherhood that was once so prominently a type of the honor and manhood of ancient Romans, and that perhaps in a higher sense is the real characteristic of Anglo-Saxons. Certainly from our worthy aborigines, the native red Americans, we can learn lessons on hygiene, as well as in many other departments of life. In encouraging attention to the laws of hygiene we directly improve public morals. Hygiene and immorality are more or less incompatible. Where education is best developed, immorality is least observable. Unsanitary conditions and filth are synonymous terms. The normal, healthy body is very likely to have a high standard of morality governing it. Therefore, the study of hygiene and the dissemination of hygienic knowledge are powerful aids in the missionary work of religion. The physician, then, in the conscientious discharge of his duties, is a valuable factor in the welfare of the community in which he lives. Cleanliness is next to godliness—a truism that medical men interpret more clearly than any others.

Respectfully,

W. THORNTON PARKER, M.D.

BEVERLY, MASS.

WHAT CAUSED THE FEVER?

To the Editor of THE MEDICAL NEWS,

SIR: In the early morning of April 1, 1892, I delivered Mrs. T., a primpara. The labor was normal and unusually easy. The pain lasted only about three hours. When I was called, the head of the child was clearly visible; *no examination was therefore necessary*. The placenta came away spontaneously in about twenty minutes. I used the secundines in a demonstration given the nurse, and I am positive that no portion remained in the uterus. There was no laceration, excepting a very minute tear of a small remaining portion of the

hymen. No injections were given, as none seemed indicated. Antiseptic pads were used.

Until the sixth day the patient's progress seemed absolutely perfect. The appetite was good. The bowels moved naturally. There was no fever. The supply of milk was abundant. The pulse was strong and regular. The after-pains were not sufficiently severe to demand attention. Involution progressed remarkably fast, and but for slightly broken sleep, not troublesome enough to alarm me, there was nothing to indicate that my patient would not be up in an unusually short time. At noon of the sixth day fever suddenly appeared, though the feeling of malaise was not sufficiently pronounced to make the young mother, an intelligent woman, think that there was anything wrong. Thinking the rise of temperature (to 105.5°) might possibly be due to decomposing coagula, with a new catheter I washed out the uterus with a 1 to 5000 bichloride solution, using a gallon of water, which returned clear, the discharges having almost ceased. There was no fetor whatever; no tenderness in the iliac region. The fundus of the uterus rose a little above the pubic bone. At 7 o'clock on the same evening the patient had one of the severest chills that I ever saw, after which the fever began to rise so alarmingly that I gave thirty grains of quinine, in two doses, half an hour apart. In the morning the temperature was normal. My satisfaction was short-lived, for at my evening visit I was obliged to record a body-heat of 106.5°. I gave quinine in the same dose as before, again flushed the uterus, with negative results, and on the morning of the ninth day found that my efforts had only succeeded in lowering the temperature to 103.5°. Quinine disagreed with the stomach; the nervous condition was bad; and the outlook seemed generally discouraging.

I was utterly unable to find any cause for my patient's condition, and thinking another case of puerperal fever might have occurred in the room we were occupying, I directed that she be moved into the large airy parlor, of which the air was to be kept very cool and frequently changed. Over her head I placed Magill's head-cooler, and ordered small doses of quinine, to be repeated at such intervals as to act as a steady tonic without disagreeing with the stomach. The fever continued very high, the temperature ranging between 106°, 105.5°, 104°; but the heart was steady, and the ability to retain nourishment (milk) was so good that I was encouraged to use acetanilide as an antipyretic, at first, commencing with three-grain doses, which never failed to depress the temperature at least two degrees, and discontinuing when the temperature fell to a safe limit. After a time, finding that no unpleasant effects followed, and that by the use of the agent my patient's nervous system was quieted, while the heart and stomach were undisturbed, I decided, if possible, to lower the temperature to nearly normal, and endeavor, by means of the acetanilide, to hold it at as nearly that level as seemed advisable. I commenced giving the drug at four-hour intervals, for I found that any effect produced lasted about that time. I continued this dose (three grains) night and day. Improvement was thence uninterrupted. My patient's jaw, which had been set so that I could with difficulty introduce my thumb into her mouth, began to relax. The temperature did not again rise above 100°; the action of the heart slowed, and the nervous system became more steady. Three days after I commenced the administration of acetanilide I stopped all medication except small doses of sulphonal to produce sleep, and no bad symptoms of any importance have since been noted.

A convert to the teaching that in private practice such cases are almost without exception avoidable, I am not a little chagrined by the fact that I can in no possible way account for the inception of this fever. I can recall no point at which possible antiseptic precautions were omitted. No portion of the secundines was retained; no coagula collected; no fetor or tenderness existed; no exposure had taken place; the breasts remained soft throughout. My nurse was careful and capable, and neither she nor myself had within two years attended a case of puerperal fever. Add to all this the fact that until the seventh day the puerperium was in all possible ways satisfactory, and I am entirely in the dark as to the cause that furnished reason for such alarm. I append a copy of my temperature-chart, hoping that someone wiser than myself will enlighten me.

LA CROSSE, WIS.

THE STUDY OF ANATOMY FROM THE PHYSIOLOGIC STANDPOINT.

To the Editor of THE MEDICAL NEWS,

SIR: I have often wondered why many medical students think that human anatomy is a dry and uninteresting study. The human body is the most wonderful piece of mechanism in the universe. In it we find a machine that is self-energizing and self-propelling; that feeds itself and at the same time consumes and carries its own fuel; that lubricates itself during its motions, and removes from it, by its own action, the waste matter resulting from its own disintegration.

If a piece of machinery could be made by human hands embracing one tithe of the perfection to be found in the human body, all mankind would hail it as a most wonderful achievement. If such be the case, may not the lack of interest shown by medical students in the study of anatomy be due to errors in our method of teaching this study?

To my mind, the first and most striking error to be found in the usually adopted method of teaching anatomy is the lack of system. Thus, in taking up the study of chemistry, we always begin by investigating the proper

ties of the gases and simple elementary bodies; thence we proceed gradually to build up the more complex compounds. An analogous method is employed in the study of botany, geology, and, in fact, in every branch of natural science, without exception.

Now, why do this in every other branch of science, and then adopt, as we do, such an entirely different method in the study of human anatomy? As a rule, we commence with the study of the adult human body, the most wonderfully complicated and marvellously organized living organism. Our usual method resembles what would be the case if, in the study of chemistry, we should commence with the study of the complex chemic carbon compounds, in place of beginning, as we always do, with the simple elementary bodies, and then gradually building up from them the compounds produced by the union of the diverse molecules.

My idea would be to entirely reverse this method of teaching. In place of beginning with the adult human body, I would begin with the human ovum in its elementary and unimpregnated state. First, I would describe the changes in the ovum occurring immediately after impregnation, then the development of the two primary layers of the ovum (the epiblast and the hypoblast), with the tissues and organs produced by them. After this, I would give the development of the mesoblast, or middle layer of the ovum, and then give the tissues and organs developed from it. In this way we would have a system of human anatomy that would be worthy of taking its place among the exact sciences.

Some great genius will do this some day soon, and we will all wonder why it was not done long ago.

Respectfully,

ROBERT REYBURN, A.M., M.D.

WASHINGTON, D. C.

NEWS ITEMS.

Presentation to Sir George Buchanan, F.R.S.—Sir George Buchanan has lately resigned the post of Medical Officer of the English Local Government Board. A committee has been formed with a view to forwarding a movement for enabling those interested in public health to give expression to the high estimation in which they hold the important work which Sir George Buchanan has done, and for affording some opportunity for the recognition of his conspicuous services in the cause of preventive medicine.

A subscription list has been opened with a view to presenting to Sir George Buchanan some permanent memento of the esteem in which he and his work are held.

Subscriptions (not to exceed two guineas from each contributor) may be sent to the Honorable Secretaries, W. H. Hamer, Ladywell, 69 Dartmouth Park Hill, London, N.W.; J. C. Thresh, The Limes, Chelmsford, Essex, or to Dr. John S. Billings, Army Medical Museum and Library, who has been authorized to collect funds for the purpose in the United States.

Vivisection.—At the last annual meeting of the British Medical Association a resolution was proposed by Mr. Joseph Hutchinson and unanimously adopted, "That this general meeting of the British Medical Association records its opinion that the results of experiments on living animals have been of inestimable service to man and to the lower animals, and that the continuance and extension of such investigations are essential to the progress of knowledge, to the relief of suffering, and the saving of life."

The American Electro-therapeutic Association will hold its second annual session at the Academy of Medicine, New York, October 4, 5, and 6, 1892. Dr. W. J. Morton, of New York, is President, and Dr. H. R. Bigelow, of Philadelphia, Secretary.

A Semmelweiss Memorial.—It is proposed to establish an international memorial in honor of Semmelweiss, who in 1847 recognized the infectiousness of puerperal fever and adopted practical measures that led to a decided reduction in the mortality from this source.

Dr. W. Thornton Parker will deliver the course of lectures on Medical Jurisprudence in the College of Physicians and Surgeons, Chicago, during the approaching session of 1892–93.

Women Eligible to Membership in the British Medical Association.—At the recent meeting of the British Medical Association the rule excluding women from election to membership was revoked.

Dr. John Deaver, one of the leading physicians of Lancaster County, died August 22d, at Buck, Pa., sixty-five years old. He was the father of Dr. John B. Deaver, of Philadelphia.

Dr. Frank P. Norbury has been elected Professor of Nervous Diseases in Marion Sims College, St. Louis.

Rudolf Demme, the well-known pediatrist, died recently at Berne.

ALL ANIMALS INOCULATED IN EYE WITH VIRULENT CULTURE TUBERCLE BACILLI

FEBRUARY 2, 1892

ANIMAL A

Control, 8 weeks after Inoculation.

Acute Inflammation of Structures of Eye. Cornea becoming cheesy.

ANIMAL A

Control, 14 weeks after Inoculation.

Inflammation has subsided. Eye destroyed. All the Cornea is cheesy.

ANIMAL B

8 weeks inoculated. Treated 6 weeks with Alcoholic Solution Bacterio-Protein.

Cornea opaque and becoming cheesy.

ANIMAL B

14 weeks inoculated. Treated 12 weeks with Alcoholic Solution Bacterio-Protein.

Disease has progressed but little. No reparative changes have taken place

ANIMAL C

8 weeks Inoculated. Treated 6 weeks with Filtrate of Liquid Cultures.

Irritation caused by treatment has resulted in Shrinking of Eye-ball, Disappearance of Tubercle and Caseous Areas. Cornea still opaque. Eyelids swollen and everted.

ANIMAL C

14 weeks Inoculated. Treated 12 weeks with Filtrate of Liquid Cultures.

All Inflammation has subsided. Anterior Chamber obliterated. Iris adherent to clear Cornea. No Tubercle or cheesy spots remain.

THE TREATMENT OF EXPERIMENTAL TUBERCULOSIS BY KOCH'S TUBERCULIN, HUNTER'S MODIFICATION AND OTHER PRODUCTS OF THE TUBERCLE-BACILLUS.[1]

BY EDWARD L. TRUDEAU, M.D.,
OF SARANAC LAKE, NEW YORK.

ALTHOUGH several attempts at preventive inoculation against tuberculosis had already been made by experimenters, the possibility of curing the existing disease by injections of products derived from the tubercle-bacillus itself originated with Dr. Robert Koch, and the gigantic human experiment that followed and resulted in so much inevitable disappointment is still fresh in the public as well as the professional mind.

The hopes to which tuberculin gave rise were entirely founded on Koch's observations of the curative influence said to be exercised by this substance upon experimental tuberculosis in the guinea-pig. In the general haste to determine its efficacy in the human subject, the study of its effects upon tuberculous animals has as yet received but little attention, and Koch himself has never given more than the most meager details of his observations relating to this most important question.

It is quite evident, however, that if products derived from the tubercle-bacillus have no beneficial influence upon the artificially-produced disease in animals, there is little reason for continuing laboratory experiments of a tentative nature on the human subject, and research must take a new direction; while, on the other hand, if these bacterial products can be demonstrated to control, to any appreciable extent, the development of experimental tuberculosis, a reasonable hope may be entertained that by perfected methods and a more exact and extended knowledge of the various complex substances produced by germ-life, the ravages of the disease in the human subject may yet be brought under control.

Moreover, the work of Hunter and the claims of Klebs would also indicate the possibility of obtaining a product, free from the dangers of tuberculin, yet capable, if not of curing the disease, at least of exercising a marked beneficial influence upon its course, and some evidence as to the remedial efficacy as well as the dangers of these various products, as noted in animals, would tend to place our knowledge on a firmer basis, strengthen our convictions and guide us to a more intelligent application of these substances to the treatment of tuberculosis in man.

The present research has been undertaken, therefore, with a view to obtaining some more definite evidence—first, as to the curative effect said to be exercised by Koch's tuberculin upon inoculated guinea-pigs; second, as to the curative value and dangers in experimental tuberculosis of the modifications of tuberculin proposed by Hunter.

Furthermore, leaving to the distinguished chemists who have undertaken it the study and separation of the various elements, remedial and injurious, contained in Koch's tuberculin, I have attempted, by an application of the eliminative process, to demonstrate, by a few simple experiments, in which part of liquid cultures of the tubercle-bacillus the remedial element resides—whether in the bacterio-protein of which the bacilli are composed, or in the albumoses and soluble toxines produced in artificial culture-media as the result of their life-history.

Treatment with Koch's Tuberculin.

The description of experiments will be made as brief as is compatible with accuracy. Twelve guinea-pigs are inoculated under the skin of the abdomen with a pure culture of tubercle-bacilli grown on glycerin-serum. Four are kept as controls, and the rest are treated within two weeks of the virulent inoculation by injections of Koch's crude tuberculin, beginning with one milligram daily, and steadily increasing to one cubic centimeter, the intervals being lengthened as the doses become larger. Great care is found necessary in order not to kill the animal during treatment by an overdose of the remedy, two of them dying within six hours of taking the same dose that they had previously borne without accident; all the animals died tuberculous, the controls with an average life of eighty-eight days, the rest of the animals with an average of one hundred and twelve days.

So far as prolongation of life is concerned, these results would, indeed, seem meager, and differ but little from those obtained by other experimenters. Dujardin-Beaumetz,[1] Gibier,[2] Jaccoud,[3] Metschni-

[1] Read before the Association of American Physicians at Washington, May 24, 1892.

koff and Roux,[4] Bardach,[5] and Pfuhl[6] all failed to cure inoculated guinea-pigs, although Pfuhl obtained a marked prolongation of life in his test-animals.

The influence of the treatment is nevertheless strikingly illustrated by the autopsies. If a healthy guinea-pig be inoculated under the skin of the abdomen, the tissues and organs almost invariably become involved in the following order: the disease spreads with great regularity from the inoculation-point to the inguinal glands; thence to the retro-peritoneal glands, the spleen, the liver and the lungs. Thus, in the dead controls the pathologic processes are seen to be more advanced the nearer they occur to the inoculation-wound, while in the treated animals the reverse usually holds true.

The controls showed at autopsy cheesy inoculation-wounds, often still open, cheesy inguinal and retro-peritoneal glands, enormous spleen riddled with tubercles and cheesy areas, enlarged tuberculous liver, and a moderate number of young tubercles scattered through the lungs. In the test-animals, if treated for more than two months, on the other hand, the inoculation-spot is healed and covered with hair; the inguinal glands are firm, only slightly enlarged, and rarely cheesy; the spleen is either moderately tuberculous, or it may even be of normal size and appearance; the liver likewise; while the lungs are solid with cheesy tubercles.

It is probable, therefore, that the curative influence of tuberculin is exercised only when tubercle-tissue has once formed. The reparative processes that it incites seem to follow in the track of the disease, but are powerless to anticipate extension to neighboring structures. Habituation to the injection soon takes place. The dose grows rapidly, as the disease, overcome at one point, spreads to another; and by the time the lungs are attacked, anything short of a poisonous amount will no longer bring about the local reaction necessary to cure.

The pulmonary disease, therefore, progresses unchecked, and soon results in the animal's death. A fact observed in the experiments further on recorded strongly confirms this view. If tubercle-bacilli are injected into the anterior chamber of a rabbit's eye, and the treatment by injections of a product of the tubercle-bacillus be begun at once, the appearance of tubercles on the iris and cornea cannot be averted, and will be rather hastened than delayed, even though the efforts of the experimenter to effect a cure be ultimately crowned with success.

That tuberculin cannot confer immunity to subsequent infection has been shown by others and by myself in a research published at the time of Koch's announcement of the specific action of tuberculin. It would seem, therefore, that injections of tuberculin exercise a marked remedial influence on the tuberculous lesions of the guinea-pig, and can cure the primary ones; but contrary to Koch's belief, the injections cannot "protect the tissues from further invasion of the germs," for infection in these animals may spread from one point to another, even while a cure of the primary lesions is being effected by the treatment.

If this view be correct, the rapidity with which the disease becomes generalized in guinea-pigs would make their restoration a most trying test of the efficacy of the remedy. It is to be hoped that Koch will, before long, give the exact details of the methods of treatment that have in his hands led to the cure of these most susceptible animals.

Treatment with Hunter's Modifications.

Whether the injurious elements of tuberculin can be eliminated or not, without impairing its remedial virtues, is a question at present of vital interest, and upon which the highest authorities differ. Koch[7] measures the efficacy of his product by its power in certain doses to kill tuberculous guinea-pigs, and from the first he has insisted that the curative substances are inseparable from those that produce fever and local reaction.

In his latest research, in which he was assisted by Brieger, a significant silence on this point is maintained. Klebs,[8] on the other hand, asserts that he has obtained from tuberculin a material entirely free from fever-producing or dangerous effects, capable of destroying the tubercle-bacillus in the living bodies of men and animals, and of curing the disease. As yet, however, he has furnished no evidence that can be subjected by others to scientific tests.

In a recent communication on the chemical constituents of tuberculin, Hunter,[9] details the results at which he has arrived in producing a modified form of tuberculin, in terms so clear and concise as to invite other investigators to test his conclusions and attempt to throw some additional light on the points he has so admirably studied. Guided by the effects observed in lupus, he has sought, while retaining the curative substance, to eliminate from Koch's tuberculin those elements that produce violent reaction and fever, which he considers principally responsible for most of the accidents caused by this mode of treatment. As a result of his research, he proposes two modifications, which he designates merely as B and C B, both of which bring about in lupus certain reparative changes tending to cure, but unaccompanied by fever, and each varying greatly in the degree and intensity of the local reaction it produces.

Some light to guide us in the application of these important deductions to the treatment of human beings has been sought by a short study of the effect of Hunter's modifications on experimental tubercu-

losis. In these products has the curative element been retained? Have the substances that produce fever and uncontrollable inflammatory reactions, or hasten a rapid generalization of the disease been eliminated? Which of the two modifications is the more efficient and safe? To these questions a partial answer has been sought by the experimental method.

Experiments.

By following Hunter's clear and concise directions no difficulty was experienced in the manufacture of the two modifications he proposes, which were obtained at first from Koch's tuberculin, and later from tuberculin made in my own laboratory. Since dialysis is depended upon in these modifications to eliminate most of the fever-producing elements, special attention was given to that part of the process. The thinnest membranes possible were selected, and the full time recommended was allowed. Nevertheless, the substances obtained, especially "B," although producing much less fever than the equivalent of tuberculin, were found to invariably cause a very appreciable rise of temperature in tuberculous animals; but no deaths occurred as the direct result of the treatment.

The details of the experiments were the same as those already described, in which Koch's tuberculin was used. The results show an average life of ninety-two days for the controls, one animal still living seven months after inoculation; an average of eighty-nine days for the animals treated with C B; and of one hundred and twenty days for the animals treated with B, of which two are still living, seven months after the virulent inoculation. The living control, however, is tuberculous; the inoculation-wound is healed, but several large cheesy glands can be felt in the groin; he illustrates admirably the extreme limit to which the element of natural individual resistance may prolong life in inoculation-tuberculosis, and the fallacy of drawing hasty conclusions as to the influence of any treatment, if based on observations made upon the prolongation of life in single animals.

Two of the animals treated with C B died unusually early, namely, sixty-three and seventy-eight days respectively after inoculation. The autopsies showed a marked tendency to early generalization of the disease; emaciation was extreme; there were no very advanced or extensive caseous processes anywhere, but an enormous amount of young tubercle was equally distributed in all the organs.

The duration of life in the animals dying while under treatment with B was considerably above the average of the controls. The autopsies showed practically the same appearances, and the same attempt at repair in the inoculation-wound, glands, and spleen, as in animals dying while under tuberculin treatment.

The two guinea-pigs that are still alive (nearly seven months after the virulent inoculation) show healed inoculation-wounds, no enlarged glands, and their weight is a trifle more than at the beginning of the experiment. The dose of modification B has risen to seven cubic centimeters at an injection; the immediate result of which is to throw the animals instantly into tetanic spasms, from which, however, they recover within an hour. They no longer show any marked rise of temperature following the injections.

From the evidence obtained by this experiment, the following conclusions seem justified: 1. In Hunter's modifications the curative principle of tuberculin has been retained. This is especially true of modification B. 2. The fever-producing elements have been, to a certain extent, eliminated, but C B may favor rather than hinder the tendency to generalization. 3. Modification B is as efficient and is safer than either C B or crude tuberculin. Thus far my clinical experience with modification B has confirmed this conclusion.

Treatment by Filtered Culture-Medium and Bacterio-protein.

Tuberculin is a most complex mixture of many hitherto-unknown organic compounds, and all attempts at solving the mystery of its chemical composition have been, as yet, only partially successful. Koch first speaks of his specific as being a 50 per cent. glycerin extract of the tubercle-bacillus; while, in a later communication, he describes it as being obtained by evaporation of liquid cultures. Whether, however, the virtues of this evaporated material are due to the extraction of the bacilli by heat, or reside in the soluble products with which they have impregnated the animal-broth during their growth, does not appear.

What is evident is that the whole is heated together, evaporated by heat, and the dead bacilli removed by filtration; the result being the complex mixture known as tuberculin.

To the bacteriologist liquid cultures resolve themselves at once into two very distinct and easily separable parts: namely, the tubercle-bacilli, which float on the surface, and the beef-broth in which they have grown. The tubercle-bacilli are principally composed of bacterio-protein, which is but very sparingly soluble in any reagent, while the liquid of ripe cultures holds in perfect solution the albuminous compounds and toxines that have been formed in it as the result of the growth and development of the microbes.

It has occurred to me that the eliminative method might here be applied with advantage, and that the future work of the chemist would be greatly simplified if it could be proved whether the remedial

principle is to be sought in the bacilli themselves or in the culture-medium in which they have grown. With this end in view the following experiments were carried out:

Liquid cultures of the tubercle-bacillus are filtered through hardened filter-paper. To this filtrate one per cent. of carbolic acid is added to preserve it, and it is now ready for use. This fluid contains all of the soluble albumoses and toxines, but no bacterio-protein, and nothing that may have been extracted from the bacilli by heat, as in the manipulation for producing Koch's tuberculin. It contains a hitherto-undescribed substance which is at once precipitated by a temperature of 100° C., and which is probably of the nature of a true toxalbumin, as it is thrown down by heat and causes fever in tuberculous animals. This substance is not a component part of tuberculin, as, in the manufacture of Koch's lymph, it must at once be precipitated by heat during the evaporation on the water-bath, and filtered off with the bacilli. Want of space forbids anything beyond a mere reference to this as-yet-unstudied element of filtered cultures.

An extraction of the bacterio-protein may be effected according to the first plan about to be described; a partial solution according to the second.

The mass of bacilli is first thoroughly washed, while still on the filter-paper, with tepid water. This is a tedious process, and should be carried on until the wash-water no longer shows any cloudiness when added to a solution of silver nitrate (the cloudiness being due to precipitation of silver chloride, caused by the presence of the sodium chloride contained in the culture-medium).

The bacilli may then be transferred to a flask containing a 50 per cent. glycerin-and-water mixture equal in volume to the original liquid culture made use of. The flask is put into the sterilizer for two hours, and after having been thus extracted the bacilli are removed by filtration through filter-paper. This filtrate is a true glycerin extract of the tubercle-bacillus, though, neither in its outward appearance nor in the effect produced by it in tuberculous animals has it apparently much in common with Koch's tuberculin.

A partial solution of the bacilli may be effected by transferring the well-washed culture-mass to an excess of boiling absolute alcohol for ten minutes, filtering while the alcohol is hot, adding an amount of pure glycerin equal to a quarter of the original volume of liquid culture used, and entirely evaporating the alcohol in the dry oven at a temperature of 55° C. This glycerin solution contains a large amount of bacterio-protein, but is so viscid that it cannot well be injected without first being heated, and even then a large needle is necessary.

With these two solutions several sets of tuberculous guinea-pigs were treated; the general observations made being that bacterio-protein solutions cause a slow form of suppuration at the site of injection; no marked fever even in very large doses (from two to three cubic centimeters); an over-dose never resulting in death, even when the animals are profoundly tuberculous. They produce no inflammatory reaction in and around tuberculous areas, and they have, apparently, no marked remedial value. They cause emaciation and general cachexia in the animals treated. From the autopsies, the 50 per cent. glycerin solution appears to hinder the natural chimiotactic reaction at the inoculation-spot or in the injected organ, and thus to favor a general spread of the disease.

Injections of the soluble products contained in the culture-medium in which bacilli have developed produce no local suppuration, but all of the characteristic reactions of tuberculin: distinct local and general reaction of a transitory nature, death invariably following an over-dose; marked improvement in the primary lesions, followed occasionally by general improvement and prolongation of life, and finally death by the spread of the disease to some distant organ, generally the lungs. By injections of this material chimiotaxis around diseased areas is greatly stimulated, a rush of leukocytes to the affected part invariably resulting from the treatment.

To obtain more conclusive evidence, recourse was had to another method of experimentation. Rabbits were inoculated in the anterior chamber of the eye according to the plan first proposed by Cohnheim and Salamonsen, and adopted by Baumgarten,[10] for the study of tuberculosis. In each experiment one group was kept as controls, while the remaining animals were divided into equal groups and treated with each of the solutions. Thus, the progress of the disease in the controls, as compared with its evolution in the eyes of the treated animals, could conveniently be watched and compared. This plan proved most satisfactory, and the evidence it brought forth is full of interest.

The Effect of Bacterio-protein Solution.

Injections of the second solution of bacterio-protein were begun from five to twenty days after virulent inoculation. They were followed by but slight, if any, fever, and caused no immediate and transitory irritation of the affected eye, which, nevertheless, steadily grew worse. They proved highly chimiotactic locally, producing suppuration at the site of puncture, and their prolonged use was followed by profound constitutional deterioration. The animals became anemic, emaciated steadily, and, if the treatment was pushed for a long time, often died of general cachexia.

On autopsy the kidneys occasionally presented the

appearance of chronic parenchymatous nephritis, and glandular abscesses and chronic pleurisy were noted. These observations confirm those of Straus and Gammaleia[11] and Muffici,[12] who found chronic poisoning to result from injections of dead bacilli. The beneficial effect on the eye-lesions was doubtful, and consisted in some cases of an apparent retardation during the second month of treatment of the destructive processes connected with caseation. The eyes were, however, never restored.

Effects of Soluble Products Contained in Filtered Culture-medium.

Injections of the filtered culture-medium in which tubercle-bacilli had been grown produced no local suppuration, only a transitory loss of weight occurring after each injection, and no serious deterioration in the animal's general health resulted. They were followed by distinct rise of temperature, varying according to the dose injected and the amount of disease present, occurring within four hours and lasting from twelve to eighteen hours afterwards, accompanied with marked but temporary irritation of the inoculated eye. Intense redness, iritis, purulent conjunctivitis developed at once, and later increased tension, cloudiness of the cornea, pannus, etc., slowly supervened, the vascular phenomena distinctly remitting during the intervals between the injections, which soon lost their irritating effect on the eye, unless the dose was steadily increased.

During the first six weeks, the treatment appears to have only sensibly hastened the progress of the disease, but about the seventh week, if the injections were begun within a few days after inoculation, an improvement in the eye-lesions first shows itself. The inoculation-wound in the cornea bulges less, and is less cheesy in appearance; the cornea is less cloudy, while no new tuberculous areas are seen to have formed on the iris. If the injections are commenced when the eye is already extensively involved, shrinking of the eye-ball and diminution of the diseased areas in the cornea are observed at this time, when destructive processes are rapidly progressing in the eyes of the untreated animal.

From this time, as the irritation caused by each injection disappears, marked improvement is apparent. The caseous areas slowly melt away, the dilated bloodvessels shrink and disappear, intra-ocular pressure diminishes, the cornea clears, and from twelve to eighteen weeks from the beginning of treatment the eye is to all appearances *cured*, in the sense that it has been restored as nearly to its normal condition as is consistent with the lesions existing when treatment was begun. The eye-ball may be but a shrunken fibrous mass, or the anterior chamber alone may be obliterated, the iris normal in appearance, adhering to the now transparent cornea, or the eye may be so little damaged that its function as a visual organ is almost completely restored. As to the permanency of this apparent cure time alone can decide. I have as yet no evidence to offer on this point, and it is not impossible that relapses may occur. The complete restoration (even if it should prove occasionally to be but temporary) of such delicate tissues, as the result of any general specific treatment, is a fact of the utmost significance and of the highest importance.

These results correspond in most particulars with those recently published by Professor Dönitz[13] and Sattler[14] in the treatment of eye-tuberculosis with Koch's tuberculin, theirs being the only observations as yet recorded in which any success has been attained in experimental tuberculosis by a specific method.

In the few autopsies made on animals whose eyes had been cured, no tuberculous disease was found in the other organs.

It should be borne in mind, however, that the anatomic conditions found in the eye are not at all favorable to a great spread of the local disease or to its rapid generalization. A study of the changes taking place during the restoration of the eye points distinctly to local reaction as an inseparable element of cure. If the dose be not increased, and, in consequence, the usual transient irritation be not produced, improvement ceases, and in time the tuberculous disease again progresses.

Attempts at eliminating from tuberculin those substances that produce local reaction would seem, therefore, to be of doubtful utility.

It is, thus, not to the bodies of the bacilli, but to the liquid that they have impregnated with the products of their life-history that we must look for the remedial element contained in ripe cultures. What is extracted from the bacilli themselves by heat in glycerinated media (as in the method hitherto adopted to produce tuberculin) cannot cure, and it is not impossible that it may hasten the spread of the disease by paralyzing the normal chimiotactic reaction of the system; besides, this substance is harmful to the health of living animals. For these reasons it should be eliminated. On the other hand, the soluble products contained in the animal broth in which bacilli have developed, but from which they have been removed by filtration without heat, can cure localized tuberculosis in the rabbit's eye, and it is to this element of liquid cultures that we must turn in future attempts to separate a substance free from the dangers of tuberculin, and yet capable of exercising, it may be, to a greater or less degree, a curative influence over visceral tuberculosis.

The conclusions to be drawn from this study may be briefly stated as follows:

1. Koch's tuberculin does not cure experimental tuberculosis in the guinea-pig, although its specific influence on the primary lesions is indisputable.

2. Hunter's modification, C B, contains less of the remedial principle than tuberculin, and is apparently quite as dangerous.

3. Hunter's modification, B, is as efficacious as tuberculin, and free from some of its dangers.

4. Solutions obtained as described from well-washed tubercle-bacilli have, when extracted with 50 per cent. glycerin and water, an injurious effect; when treated with hot alcohol, a doubtful and, at best, feeble remedial influence over experimental tuberculosis.

5. They produce suppuration and serious constitutional impairment, which may result in organic disease and death.

6. The liquid culture-medium in which tubercle-bacilli have developed, but from which they have been removed by filtration, contains the elements that bring about reaction and cure in tuberculous tissue.

7. Experimental tuberculosis in the rabbit's eye can be cured by injections of the filtered culture-medium.

8. The permanency of such a cure has not yet been established.[1]

THE ECZEMAS OF INFANCY AND CHILDHOOD, WITH SPECIAL REFERENCE TO ETIOLOGIC AND DIETETIC CONSIDERATIONS.[2]

BY CHARLES P. RUSSELL, M.D.,
OF UTICA, N. Y.

THE types of eczema to which I invite your attention in this paper are the pustular, vesicular, erythemato-squamous, and seborrheal, the principal varieties ecountered in infancy and childhood.

That these varieties of eczema in the young are very frequently the local expression of hereditary taint, with consequent depraved cell-action and poor nutrition will, I think, be readily acknowleged by all who have much to do with skin-diseases, and a firm belief in the importance of considering these troublesome affections of the young from the standpoint of etiology, as bearing upon successful management, must be my excuse for bringing this subject before you.

Whatever affects the general nutrition of the body must necessarily influence the well-being of the skin, for that structure, as much as any other, depends upon normal blood and perfect cell-metabolism for its health and physiologic activity.

Broadly speaking, it may be said that there are two classes of influences at the bottom of imperfect skin-nutrition and predisposing to catarrhal inflammations: hereditary taint, as affecting normal cellular activity, and acquired poverty of the blood and tissues, the result largely of disorder of the digestive apparatus.

I will not consume valuable time by a consideration of the digestive processes in infancy and childhood, as you are all doubtless familiar with them. It is enough for our present purpose to show that the anemia and tissue-debility resulting from improper feeding in the young is a powerful factor in the causation and persistence of their eczemas.

If we glance at the differences in structure between the cutaneous envelop of the infant and that of the adult we will see reason why that of the young and growing child is more disposed to take on inflammatory action. In infancy the circulatory and nervous systems of the skin are developing and expanding with great activity, the tissues are young and succulent, the capillary circulation is very active, the lymph-channels and lymph-glands are relatively large, and the sensory nerves are extremely impressionable and easily irritated.

A distinguished British writer, Stephenson, aptly says: "It is dependence upon development which distinguishes the eczema of the child from that of the adult. Under its influence we see its character modified according to the age of the child; we find it obstinate under treatment at the earlier stage and amenable to it or undergoing a spontaneous cure as the period peculiar to it draws to a close." This author places the limit of the period of extreme liability to catarrhs of the skin at six years. From my own experience I can indorse Stephenson's dictum, and say that eczema of any variety, but more particularly the pustular and vesico-pustular, is more severe, more rebellious to treatment, the more nearly its time of development approaches to birth. This

[1] The paper was followed by a demonstration of the curative influence of the treatment by means of photographs and living animals.

[2] Read before the Section of Dermatology and Syphilology of the American Medical Association, at Detroit, June, 1892.

is especially true, I think, of eczema impetiginodes, whether depending upon a scrofulous taint or upon simple debility.

Eczema pustulosum is preëminently the type of scrofulous eczema, although at times it is encountered in children who are simply anemic or poorly nourished. When the scrofulous taint is the marked predisposing factor the disease seems to develop at an earlier age than when it is the expression of anemia and malnutrition alone, and the more pronounced the element of struma in any case the more subacute the catarrh, the more sluggish the reparative processes, and consequently the more rebellious to treatment.

When we ask just how the strumous taint acts upon the nutrition of the skin we ask a question that pathologic histology has not yet enabled us to answer definitely.

From the pathologic studies of Neumann and others we know that in scrofula the lymph-channels are enlarged, dilated, and in places more or less obstructed by the excessive formation of the small, round lymph-cells or lymphoid corpuscles.

This process, being a general one, must take place, to a greater or less extent, in the lymph-spaces of the derma, which we know also from the investigations of Neumann, are relatively larger in the scrofulous than in the healthy skin.

If this be so, it seems reasonable to suppose that the resulting pressure upon the vascular structures and cells of the corium must interfere with and prevent normal nutrition. Be this as it may, clinical experience shows that there is a peculiar, depraved nutrition of the skin of the strumous child, which extends at all times an invitation to eczema. In many cases of pustular eczema we cannot find any external cause, or the external irritation is only very slight and transitory in action.

When external irritants coöperate with hereditary taint in producing an eczema, the part played by the irritant is oftentimes very slight and of secondary importance. A prominent external factor in some of these cases is the decomposition of the fatty acids of the sebaceous secretion, which is often abnormally abundant in debilitated infants. This excess of production is at times especially marked upon the scalp, neck, forehead and buttocks. Among other sources of external irritation, besides accumulation and decomposition of the natural secretions, from lack of cleanliness, may be mentioned too frequent bathing, immoderate friction, the use of coarse super-alkaline soaps, acid excretions left in contact with the skin, prolonged contact of catarrhal discharges from mucous surfaces, over-sweating and maceration of the epidermis from too much or too warm coverings, piercing the ears, and scratching to relieve punctures from various causes.

Treatment. The pustular or impetiginous eczema of the young depends so largely upon the influence of diathesis that to be efficient its treatment must consist primarily of measures calculated to increase nutrition. Purely local treatment is in many cases insufficient, and must necessarily be so when we consider the vicious constitution, the anemia and debility so often at the root of the disease.

Many obstinate cases of eczema pustulosum in nursing children are rendered more so by the child being half starved on account of the poor quality of the mother's milk. These cases begin to improve very rapidly after the substitution of a healthy wet-nurse, if that is practicable, or, if that cannot be afforded, good cow's milk, properly diluted according to the age of the infant. I think it best in most cases to give the milk in its natural undigested state if there be no catarrh or marked weakness of digestion. In warm weather, milk can be kept from decomposing by the usual process of sterilizing by heat and then preserving in tightly covered, absolutely clean jars in a refrigerator or other cool place. In the ordinary run of cases this seems to me much better than peptonizing it. The bitter taste of peptonized milk, when overheated, makes it very unpalatable, and we have all seen it a difficult matter to overcome the repugnance of some infants to it. If for any reason the infant cannot digest the milk after a fair trial, a resort may be had to the peptonized article, until the child's digestive processes have become stronger. Some illy nourished, puny little ones I have found will digest an artificial food like Nestlé's or Carnrick's better than milk in any form. Condensed milk I mention only to condemn as a food for an eczematous infant. It contains too large a proportion of saccharine matter, and too little of the true strength-giving elements. Whatever line of dietetics the little patient is put upon, the important thing is to select the most nourishing food that is at the same time the most digestible—the aliment that is most easily digested by the patient under treatment, for it is the patient you have to treat as well as the disease.

I have found emulsion of cod-oil particularly useful in eczemas associated with struma, especially one known as peptonized cod-liver oil and milk. In my hands the administration of this has been productive of much benefit, not only in the scrofulous child, but when malnutrition, pure and simple, seemed to play a part in maintaining the eczema. In the case of bottle-fed infants, the peptonized oil and milk may be added directly to the cow's milk, or be fed from the spoon in doses of a teaspoonful from four to six times a day. In nursing infants, when the natural food seems to be thin and lacking in fatty matter, the oil may be given through the medium of the mother. For this purpose I

think very well of the combination of cod-liver oil and malt, as uniting a nutrient with an agent promoting assimilation and lactation.

Infantile eczema, whether vesicular or pustular, when some degree of anemia exists, is often much benefited by the administration of some form of iron. The syrup of iron iodide is indicated and is a most useful hematinic in the anemia of scrofulous eczema. In the simpler forms of anemia resulting from poor food, bad air and want of sunshine, I have found ammonium and iron citrate and the lactate very assimilable and unirritating forms of iron. Lately I have used a syrup of ferric chloride in some cases of eczema with impoverished blood, and have found it exceedingly well tolerated by very young children and very prompt in its effects.

In all varieties of infantile eczema, constipation, if present, must be corrected. This should always be attended to at the outset, before the regular line of treatment is instituted. We often meet with obstinate constipation in eczematous infants at the breast, there seeming to be some constipating quality of the milk. In other cases the constipation is evidently due to a deficient secretion of bile, as shown by the sallow skin, furred tongue, and clay-colored stools. I have found granules of podophyllin, gr. $\frac{1}{10}$, useful in relieving constipation of this sort. In some few cases the podophyllin may irritate a little. If it does, it may be advantageously replaced by calomel in doses of from gr. ½ to gr. 1 three times a day, for a few days, until the liver has been well acted upon, and the tongue becomes clean; or the combination of rhubarb, mercury with chalk, and soda may be given. When constipation seems to be due to some alteration in the quality of the mother's milk the infant may be given from ten to twenty grains of sodium phosphate in a little warm, diluted milk, night and morning; or the extract of malt may be administered in doses of a teaspoonful, added to the milk. The non-bitter fluid extract of cascara, in combination with malt, I have found serviceable in treating the constipation of children with eczema. It is particularly useful as a tonic to the glandular structures after hepatic torpor and derangement has been corrected. It has also the advantage of containing a diastasic nutrient. Many children with eczema suffer more or less from a mild gastric catarrh. This favors the spread and increases the tenacity of eczema. We may combat this with small doses of calomel, say gr. ½, or of mercury with chalk, say gr. 1, three or four times daily for a few days, followed by bismuth or ammonium citrate.

Vesicular eczema. It is a peculiarity of vesicular eczema, as distinguished from the more pustular form in young children, that it tends to invade a much larger surface. We see it is not so much restricted to the face and scalp and contiguous regions. It is a common thing to see not only the head, but considerable portions of the trunk and upper and lower extremities invaded by it. It is commonly presented to us in the beginning of its second stage. We then have the common picture of an intensely reddened, swollen, itchy, exuding surface; the discharge drying into yellowish scales and crusts; or where exudation is not so abundant, the exposed red, raw, bleeding mucous layer. Typical vesicular eczema occurs in a class of children of better general health than obtains in the lymphatic or strumous form. It is not so essentially dyscrasic in nature, but it is oftener the expression of constitutional states and acquired blood-conditions. In most cases these acquired states coöperate with external irritation in evoking the eczemas of the vesicular and erythematous types. As the result of my own observations, I should say that external irritants play a much more important part as factors in the causation of vesicular eczema than they do in the pustular or impetiginous varieties.

Scrofulous eczema is more often the result of a congenital morbid impression on the skin, alone or in association with a mild irritation. The non-diathetic eczema is more often the result of acquired conditions coöperating with external irritation of a more pronounced character. We must also take into account the fact that the non-strumous integument is thinner, has a more active capillary circulation, and is thereby rendered more responsive to both external and internal forms of irritation. All conditions producing reflex irritation of the skin, such as delayed and difficult dentition, repeated attacks of acute indigestion, gastro-enteric catarrhs, intestinal parasites, are prominent among the internal causes of vesicular eczema in infancy and childhood.

The bronchial asthmas of rickety children. There is a peculiar alternation sometimes seen between bronchial asthma and eczema in rachitic children, the one acting substitutively for the other.

In children, from two to six years of age, we occasionally meet with eczemas tending toward an erythemato-squamous type, attacking the back, the gluteal region, and lower limbs. In many of these cases I have found the urine habitually hyperacid from excess of urates, depending upon a suboxidation of imperfectly digested food, usually containing an excess of the nitrogenous elements. The little subjects are often plump, and apparently well-nourished, but all are pale, with dry and harsh skin, furred tongue, and irregular action of the bowels. This erythematous eczema, which early passes into the squamous stage, is likely to be associated with an overacid condition of the system. Very often we find that these little subjects have been allowed tea and coffee, and that fried dishes, meats, pastry, and other unsuitable articles have

entered largely into the dietary. The first and most important thing to do in assuming charge of such a case is to eliminate at once from the diet-list all nerve-stimulating beverages and rich, indigestible food. The food taken should be mild and unstimulating. There should be a judicious admixture of nitrogenous and carbohydrate aliments, not reaching excess in either direction. Powdered beef-peptonoids is a good dietetic preparation; I have found it of much service when digestion was weak, it being nourishing and at the same time not overstimulating. Some chronic weeping and scaling eczemas in children, associated with a scanty, heavy urine, are much benefited by the administration of alkalies. I prefer the vegetable acid salts of potassium for children, as they are better borne by the stomach and diffuse more quickly into the blood. Potassium acetate is most useful in this connection, given in from five- to ten-grain doses, well diluted, after meals. It can be given with a tonic, such as nux vomica or cinchona, if there is much general debility. The liquor potassii citratis may also be given with good effect in these cases.

Whatever diversity of opinion there may have been with regard to the efficacy of arsenic in the scaling eczemas of adult life, there is, I think, practical unanimity in favor of its use in the squamous stage of the disease in the child. Personally, I may say that I have seen prompt improvement follow the exhibition of arsenic in infantile scaly eczema. It seems to be more especially useful in thin, nervous subjects. Young subjects will bear relatively larger doses of arsenic than adults, there seeming to be a parallelism between their tolerance of this drug and that so often manifested for mercurials. In the papular eczemas arsenic is generally useful. Typical papular eczema is not very frequently encountered in children under six. It is sometimes advantageous to combine small doses of arsenic with potassium acetate or citrate. The indications for this union of two valuable therapeutic agents are the usual urinary indications for an alkali and a sluggish subacute state of the eruption, a prolonged halting in the stage of repair.

The several forms of eczema in the first years of life may be found in children who seem to be perfectly healthy, presenting no evidences of inherited or acquired disease, and no marked symptoms of functional derangement. In this class the determination of catarrhal disturbances of the skin may be wholly due to external irritation. In others the train is fired by some temporary nerve-irritation acting reflexly upon the skin, such as teething, the sudden change from a milk-diet to a diet of farinaceous and animal food. Furthermore, in searching for the cause we can in a considerable number of cases only content ourselves by saying that the child has an inherited predisposition to eczema, making it easy for any external irritation to evoke the disease.

Eczema seborrhoicum is occasionally met with during infancy and early childhood. If we are willing to extend the use of the term to simple collections of fatty scales upon the scalp, making that the first stage, as Unna does, then it is a relatively common disease in children. In its more pronounced form I do not believe that it is very frequently met with in the very young subjects whose eczemas are the subject of this paper. In my experience it does not seem to be generally associated with a depraved constitution or impaired general health. Certainly, most of the cases that I have seen have been in healthy children, although I have seen a few associated with a scrofulous taint. Whether that had any predisposing influence or not, I am not prepared to say.

Eczema seborrhoicum in its second stage, presenting oval and round dull-red, slightly elevated macules, covered with crumbly, greasy scales and crusts, the individual spots enlarging and coalescing, is sometimes seen upon the faces of very young children. In them it does not, however, show the same disposition to extend rapidly downward that it does in adolescents and adults. The more nearly we approach infancy the more often do we meet with it in the first stage, or as a so-called seborrhea sicca capitis. With each added year of life the disposition to assume the crusted and moist form is intensified. Most of the cases do not seem to require any internal treatment, the subjects being usually in good or at least fair health. If in any case we discover functional derangements of the stomach, bowels, kidneys, or liver, these deviations should, as far as possible, be corrected at once, just as in the treatment of any other variety of eczema. If we find the disease associated with inherited struma, syphilis, or any other constitutional taint, the alterative and tonic treatment applicable to these dyscrasiæ is certainly indicated, in addition to efficient local applications. In the internal treatment of seborrhoic eczema there is one remedy that I have used in a few cases and, I think, with some benefit, and that is ichthyol. In those few cases it has been well borne, and has seemed to shorten the duration of the disease. I have given it in doses of from one-half to three grains, in pill, according to age.

From what has been said in this paper concerning the nature and etiology of eczema in infancy and childhood, the following conclusions may be drawn:

1. A large proportion of infantile eczemas have for their basis an inherited constitutional taint or dyscrasia.

2. In a certain proportion, and a fairly large one, anemia and malnutrition act as predisposing causes,

impressing upon the disease a tendency to chronicity and rendering it less responsive to local treatment.

3. Eczemas originating during the first year of life are usually more obstinate than those arising later, and in them constitutional treatment is very important.

4. The eczemas occurring during the early years of childhood, between two and six years of age, generally takes on the more typical vesicular type. They are rather vesicular or erythematous than pustular, and external irritation plays a relatively more important rôle in their production.

5. The internal predisposing cause in these eczemas is oftener some acquired condition than an hereditary one.

6. Dietetic, in addition to alterative, treatment is most important in the strumous eczemas of infancy. Cod-liver oil, malt, and iron iodide are the best constitutional remedies, either alone or in combination to suit individual conditions.

7. In the internal treatment of the vesicular and erythematous eczemas of early childhood, remedies addressed to the correction of acquired states and functional derangements of the chylopoietic system are more often indicated. Malnutrition and anemia must first be removed by simple, easily-digested food. Dyspepsia, gastric irritation, intestinal catarrh, hepatic torpor, and deficient kidney-action must all be treated and removed by appropriate remedies, before any striking effects can be obtained from local applications.

THE EFFECTS OF HEAT AS MANIFESTED IN WORKMEN IN SUGAR-REFINERIES.

BY W. M. L. COPLIN, M.D.,

ADJUNCT PROFESSOR OF HYGIENE, DEMONSTRATOR OF PATHOLOGY, CURATOR OF THE MUSEUM, JEFFERSON MEDICAL COLLEGE; ADJUNCT PROFESSOR OF PATHOLOGY, PHILADELPHIA POLYCLINIC; A. A. SURGEON, M.-H. S.; PATHOLOGIST TO ST. AGNES' HOSPITAL;

D. BEVAN, M.D.,

INSTRUCTOR IN HYGIENE AND INSTRUCTOR IN CLINICAL MICROSCOPY, JEFFERSON MEDICAL COLLEGE; BACTERIOLOGIST TO ST. AGNES' HOSPITAL;

AND

H. SOMMER, JR.

ON Monday, July 25, 1892, the temperature of the city of Philadelphia had been gradually creeping up until it reached blood-heat. Mr. W. W. Harrison, representing the Franklin Sugar Refining Company, sent a note to Dr. Coplin stating that, by reason of the extreme heat outside and of the still higher temperature in many parts of the refinery, the men were beginning to show evidences of suffering, and requesting that arrangements be made for giving all who might present themselves professional attendance in the refinery.

An accident-room had been fitted up upon the ground floor of one of the coolest buildings. The room is fifteen feet square, has two windows opening into the street and a door opening into the refinery. The floor is of concrete, and the walls and ceiling are plastered and painted. There is no ingress of air from the refinery proper except through the door when open. In anticipation of being utilized for the treatment of accident-cases, this room had been fitted up with a medicine case, a desk, a table, an ice chest, a large, flat bath-tub, hot and cold water, a bed, and two large stretchers. Illumination is furnished by four incandescent burners, one of which is portable and can be carried conveniently to any part of the room. There is a full complement of medicines that may be needed for emergencies, thermometers, bandages, antiseptic dressings, splints, record-sheets, and books for making the necessary notes of an emergency hospital. The temperature of this room on the hottest days ranges from 95° F. to 100° F. By reason of the extreme heat, a blast, six inches in diameter, was arranged along the ceiling of the room, with angular tubes, projecting downward and so placed that they can be turned in any direction; by means of slides placed in the opening the blast can be fully regulated or shut off from any one or more of the tubes. This blast is connected with a ventilating fan driven by an electric motor, securing between 1500 and 2000 revolutions per minute and delivering air, brought from the street, through a large funnel containing filtering sieves, into the room with a current sufficiently strong to lift the hat from one's head if standing at a suitable angle. A thermometer in an air tight box would register 95° F.; if kept in the current of air the registration would be from two to five degrees lower, and the constant change of air rendered the room pleasantly cool.

The temperature of the water from the ordinary supply was about 80° F., so that water from an artesian well, with a temperature of 45° F., was piped in at such pressure as to furnish a fine spray of enormous force.

The temperature throughout the different parts of the refinery varied from 95° F. to 165° F. Some of the men worked constantly in temperatures of from 115° F. to 118° F., and although the building is abundantly supplied with ventilating fans, run by both steam and electric motors, there prevailed a stillness that was absolutely oppressive. The men are for the most part foreigners and accustomed to the work, which, although in a sense laborious, is so arranged as to require no continuous labor in very hot places for any one individual. The foremen of the different departments are intelligent and well trained, and to these were issued instructions that should anyone complain of any symptoms whatever, or show any evidence of illness, he should be brought to the accident-office for examination.

Arrangements were perfected by which Mr. Henry Sommer, Jr., should be constantly on duty and Dr. Coplin and Dr. Bevan on duty during certain hours.

The number of men on duty in the various departments numbered 800 in the day and 500 in the night. The shifts of men changed at 6 o'clock in the evening and at 6 o'clock in the morning. The number of cases treated, with the temperature out of doors, and the results of treatment were as follows:

	Highest Temp. out of doors.	Number treated.		Returned to work.	Sent home.	Sent to hospital.	Fatal.	Total.
		A. M.	P. M.					
Monday, July 25	93°	...	13	9	3	1	1	13
Tuesday, " 26	101	32	37	58	11	...	...	69
Wednesday," 27	95	23	14	33	4	...	...	37
Thursday, " 28	96	15	24	32	7	...	...	39
Friday, " 29	98	21	17	35	2	1	...	38
Saturday, " 30	87	5	9	13	1	...	...	14
Sunday, " 31	80	1	1	2	...	...	...	2
Monday, Aug. 1	...	1	...	1	...	...	...	1
		98	115	183	28	2	1	213

Of this number, it will be observed, 183 returned to work; 28 were sent home; 2 were sent to the hospital, and 1 of these died. The temperature of the men ranged as follows: In 2 the temperature was over 108° F.; 1 of these died (temperature 110° F.), 1 recovered (temperature 108.8° F., rectal). In 28 the temperature ranged between 105° F. and 108° F.; in 7 of these it was above 107° F.; in 11 above 106° F.; in 10 between 105° F. and 106° F. In 50 the temperature ranged between 102° F. and 105° F.; in 17 of these it was above 104° F.; in 13 above 103° F. and below 104° F.; and in 20 between 102° F. and 103° F. Of the remaining 133 the temperature in 62 was above 101° F.; in 49 it was between 100° F. and 101° F.; in 8 between 99° F. and 100° F.; in 6 between 98° F. and 99° F.; in 5 between 97° F. and 98° F.; in 1, 96° F.; in 2 between 95° F. and 96° F.

As to the hours at which the men became sick: 102 cases occurred in the twelve hours following midnight, 111 in the twelve hours following midday. Of the four quarters of the day, 57 cases developed between midnight and 6 A.M., 45 between 6 A.M. and noon, 66 between noon and 6 P.M., and 45 between 6 P.M. and midnight. The larger number of attacks occurred at or about the changes of shifts, namely, between 3 o'clock and 5 o'clock, A.M. and P.M. This would be expected, as at those times the men had been exposed to the heat for several hours and the lunch at 12 o'clock had had time to lose its invigorating effect.

The humidity seemed to be a most important factor in the development of the attacks. Thus the great majority of the cases occurred in the boiler-room, the air of which contains escaped steam and is of relatively high humidity, and in the "mixer," where the raw sugar is emptied into the melting-reservoir, over which the men work and where there is constantly present a large quantity of aqueous vapor. There is also a relatively high degree of humidity where the centrifugal machines are running, which is partly overcome by the forcing in of large quantities of cool air, keeping the temperature down, but not proportionately reducing the danger.

From the temperature-records it would also appear that temperatures several degrees higher can be borne if the atmosphere is dry than if it is moist. In the boiler-house the temperature varied from 120° F. to 132° F., averaging between 122° F. and 124° F., with no great percentage of cases, while on the machine-floor, with a temperature between 112° F. and 120° F., averaging from 115° F. to 117° F., with a high degree of humidity, 60 cases developed. New men, unaccustomed to the work, suffered more than the old hands. Men who had been able to eat and sleep while off duty rarely became prostrated, while of those unable to eat and sleep during the hours of rest few escaped. All of the men, at least the larger percentage, drank beer freely, and many claimed that it enabled them to better withstand the effects of the heat. There was certainly no evidence of their suffering as much as those who drank but little or none at all. Those who drank largely of the water were extremely prone to suffer.

SYMPTOMS.—The most constant symptom, and the one of which the patient complains the most, is "cramp," usually referred to the region immediately below the ensiform appendix, not infrequently associated with similar pain in the calves of the legs, occasionally in the back, sometimes also in the hypogastrium, less commonly in the thighs and in the upper extremities. The patient also complains of difficulty of respiration, as though a weight were on his chest. Occasionally there is pain in the splenic or hepatic region. In nearly all of the cases headache is present, the character of which, according to the patient's statement, is sharp and throbbing; it is usually temporal or supra-orbital, rarely occipital. In some of the cases nausea was present; vomiting rarely occurred. The patient is agitated; muscular movements are executed in a jerky manner; the skin is pale, usually cold and clammy if the temperature is below 102° F. or 103° F.; rarely will the surface-temperature

be high. The axillary temperature is not always to be depended upon; in the fatal case, to be narrated later, the axillary temperature was only 105° F., while the rectal temperature was 108° F. In a few of the cases diarrhea was present; in the majority constipation preceded the attack.

Consciousness rarely wavers until the temperature passes 106° F. Its gradual loss may be briefly outlined as follows: The patient feels sick at stomach, and may even attempt to vomit; there is vertigo; the pupils sluggishly respond to light but not in accommodation. The eyes are vacantly fixed, the lids move slowly and infrequently; the voice wavers, often becoming sepulchral.

This condition slowly passes into delirium, which occasionally becomes active and at times fierce and uncontrollable, and during which convulsive movements may occur; these usually begin in the extremities, but may, later, involve the muscles of the trunk, more particularly those of the back, and occasionally those of respiration, giving rise to interference with breathing and cyanosis. During the convulsive seizure the arms are drawn closely to the sides and the elbows backward, so that the patient may rest upon the elbows and heels or elbows and buttocks; the head is rotated from side to side; respiration is sighing, occasionally moaning; the pupils do not respond to light, and not infrequently the lids are spasmodically closed; the pupils may be unequal. The patient swallows with difficulty, if at all. As the temperature cannot be taken in the axilla or in the mouth, the rectum must be depended upon. The mercury in the thermometer rapidly rises to 106° F., 108° F., and 110° F., or even higher, and unless the temperature be speedily reduced death must ensue. In the milder cases the temperature is below 105° F.

Speech may be jerky. There is intense headache. The skin may be moist, or it may be dry; if moist, it is cold and clammy. In either case the skin and lips are pale. The conjunctiva is brilliant. The ears are cold. The finger-nails are blue or of an ashen whiteness. Not infrequently there is tenderness in the hepatic and splenic regions. Untreated, these cases, as a rule, become transformed into a graver type. Removal from the heated surroundings to a cooler place does not entirely prevent their progress, and the large majority of cases become progressively worse. If the case progresses unfavorably, coma sets in. In fulminating cases coma may develop without any precursory symptoms.

The cardiac impulse is diffused, as though the ventricles were distended and the organ laboring. The pulse is "floody," a term coined to express the condition. To the finger it is like a sudden flood of blood coursing in the channel of the vessel, and disappearing upon the slightest pressure. Irregularity in the pulse and in the cardiac rhythm is a constant feature. There is ordinarily no increase in the intensity of the heart's sounds, certainly no accentuation.

The urine is scanty and high-colored, and when the pyrexia becomes excessive albumin may be temporarily present in small quantities. There is a constant desire to urinate, though often no urine is voided. There is pain in the cervical region, more particularly posteriorly, on either side of the median line. There is almost invariably pain in the back, and in a few cases girdle-pains were present.

The patient may be conscious of the high temperature; but, as a rule, he feels cool, not infrequently chilly when brought out of the intense heat. In a number of cases in which the temperature ranged about 105° F. a blanket felt comfortable. The pyrexia is, as a rule, not appreciable on the skin or surface during consciousness.

In one case cyanosis manifested itself. In the milder cases the temperature ranges from the normal to 102° F. The patient complains of flushes of heat alternating with chilliness. There is great thirst. Removal from the extreme heat will often be followed by a gradual return of the temperature to the normal, and only weakness, entirely disproportionate to the other symptoms, remains.

Diagnosis.—There is, of course, no difficulty in making the diagnosis of a well-developed case of thermic fever in which the temperature is characteristically high. Cases of this kind, unfortunately, are not those in which mistakes are made, and there is but one condition with which they may be confounded, namely, uremia. It is scarcely possible to mistake thermic fever for apoplexy. The temperature would in almost all cases be the guiding point, and the marked disparity between the internal and surface temperature will always lead in the right direction. One of the cases that did badly in treatment, and which afterward died, presented many of the features of uremia. We must confess that the breath had a distinct urinary odor. There were convulsive seizures, and the moaning and gritting of the teeth not uncommonly observed in uremia. There was no urine in the bladder. Of course, the temperature is the diagnostic point of dependence. We are convinced that many of the milder cases are mistaken for cases of ordinary cramps, enteralgia, or intestinal indigestion, by reason of the abdominal pain that is almost invariably present. The patient, however, who has had cramps or intestinal indigestion will immediately recognize that there is a difference in the character of the pain: there is besides some elevation of temperature—not sufficiently great, however, to make the diagnosis positive. In the earlier hours of the attack the temperature will usually range from 102° to 104° F.

The skin will be cold and clammy; nausea will be present, occasionally vomiting. The character of the cramps is an important factor in making the differential diagnosis. They are more frequent than in ordinary enteralgia, and are not relieved by counter-irritants, pressure, or hypodermatic injections of morphine. In one case, a grain and a half of morphine were administered hypodermatically without effect upon the pain. Such a condition will often aid in making a diagnosis.

PATHOLOGY.—The consideration of the pathology has been deferred until after the consideration of the symptoms and diagnosis, on account of its hypothetical character.

The pathology of thermic fever is obscure. The most lucid observations upon the subject are those of Professor H. C. Wood. The fever itself is held to be "due to paralysis, under the influence of the extreme external heat, of the center in the medulla which regulates the disposition of the bodily heat. Owing to this disturbance more heat is produced while less is given off than normally" (Osler). This statement is but a juggling of words, and expresses neither the morbid anatomy nor the pathology of the condition. That there is venous engorgement is, in a sense, true, but it is not entirely so. Probably the apparatus more particularly affected is that portion of the circulation included in the portal system. Here, no doubt, the blood accumulates in the largest quantity, as may be inferred from the facts that follow.

The area of hepatic percussion-dulness is enormously increased, and, as a rule, in proportion to the intensity of the attack; when the overlying abdominal wall or the distended intestine permits of careful splenic percussion it will likewise be found that the area of splenic dulness is increased. The location of the pain corresponds with that observed in some of the forms of malaria in which hepatic and splenic congestion is a prominent feature. Again, the surface temperature of the abdomen is higher than that of any other part of the body; the rectal temperature is from two to three degrees in ordinary cases, and from three to five degrees in more severe cases, higher than the temperature of the mouth, which in turn is one or two degrees higher than the temperature of the axilla. Other features suggestive of an accumulation of blood in the viscera are the extreme pallor of the skin, the inability to produce redness by ordinary methods and the difficulty that attends attempts at blood-letting. In the one case in which blood-letting was resorted to, the blood was extremely dark. It clotted with usual promptness, but showed no other evidence of alteration than the intense darkness.

The cause or causes that determine an accumulation of blood in the viscera probably act in one of two ways, or possibly both: (1) Contraction of the cutaneous capillaries under the stimulus of the extreme heat, thus diverting the blood to the viscera; (2) Paralysis of the vascular apparatus of the portal and possibly of the pulmonary system, favoring stagnation. Which is the correct hypothesis cannot at present be stated. Good reasons may, however, be presented in support of each.

The cause of the headache is probably the intense cerebral congestion. The absence of muscular fibers in the cerebral arterioles is in favor of the view of stasis. The cramps are probably abortive convulsive seizures due to the interference with excretion and the retention of metabolic products, closely resembling the condition in eclampsia. It is not necessary to refer to the degenerative changes that have been found in the viscera post-mortem, as it is not probable that they occur in cases in which recovery takes place.

PROGNOSIS.—The prognosis is largely dependent upon the time at which the patient comes under observation. Before consciousness is lost the prognosis is extremely favorable. In the case of a man who staggered into the accident-room, unable to give his name, check-number, or address, and in whom the temperature was 106.5° F., recovery was rapid under treatment, and the man returned to work, contrary to our advice, and so far as we are aware suffered no inconvenience afterward.

Apart from early treatment, the prognosis will depend almost entirely upon the temperature. If this does not exceed 105° or 106° F., recovery is the rule; if the temperature be higher the prognosis is less favorable, although very high temperatures are not necessarily fatal. In cases in which the temperature reaches 107° or 109° F., the patients almost always recover, provided the pyrexia is not long continued.

Age is a determining factor in prognosis. The old are less favorable subjects than the young. The habitual use of alcoholic stimulants has been supposed to render the prognosis in individual cases more grave, and as the laborers in the refinery, mostly Germans, habitually drink large quantities of beer, perhaps whiskey and other intoxicants, one would suppose that the mortality must necessarily be large. This has, however, not been our experience. A man with the alterations of tissue and function that accompany the habitual use of alcohol would be more likely to succumb than one in health; thus chronic catarrhal conditions of the stomach and cirrhosis of the liver must add materially to the gravity of the case; that alcohol *per se* does so is doubtful.

TREATMENT.—The treatment of cases in which there is elevation of temperature may be summed up in the injunction, "*increase the peripheral cir-*

culation;" anything that will accomplish this end will help the patient. If the skin can be made intensely red, and the pulse, which may not be perceptible at the wrists, can be brought up, the patient will immediately feel better, and in the large majority of cases consciousness will at once return. While under ordinary circumstances the restoration of the activity of the cutaneous circulation is easy, in thermic fever it is not so. In the treatment of our cases, large undressed sponges, gritty and hard, were freely used by two muscular assistants. In all of the cases except the fatal one and another to which we shall refer later, cutaneous redness was secured in from three to fifteen minutes. With the restoration of an active peripheral circulation the symptoms rapidly subsided. Remedies that attain this end may here be used to advantage. Atropine seems certainly indicated, and in our hands has given excellent results. If less than $\frac{1}{60}$ of a grain be given hypodermatically at a dose the medicament is wasted; in severe cases $\frac{1}{40}$ or even $\frac{1}{30}$ of a grain may be used, preferably in two doses, with a brief interval —say, of five minutes.

Aromatic spirit of ammonia acts happily and is the only medicament which acts with equal promptness when administered by the stomach or subcutaneously. It should be given in doses of from half a dram to a dram in milk. Morphine in doses of not more than a quarter of a grain may be advantageously combined with either aromatic spirit of ammonia or atropine. Strychnine does good in cases in which there is great prostration or inordinate muscular weakness. The nausea is best combatted with cracked ice.

Toward the close of the epidemic the advisability of employing amyl nitrite was discussed, on account of the promptness with which it induces a peripheral determination of the blood. The drug was used in but one case, but with the most gratifying results. A "pearl" containing three minims was crushed in a handkerchief and the patient allowed to inhale the vapor freely. The headache and cramps immediately disappeared like magic, and the temperature, which had been 102.6° F., fell in a few minutes to 99° F. No other medicament was used. Half an hour after the treatment the patient felt entirely comfortable, with the temperature normal, and after the administration of morphine sulphate, grain $\frac{1}{4}$, and atropine sulphate, grain $\frac{1}{40}$, hypodermatically, he proceeded home and reported for work on the following day. Although we have not employed nitro-glycerin, it seems probable that it might be advantageously substituted for amyl nitrite. Ice applied to the head will alleviate the headache.

The reader has, no doubt, ere this, expected that each successive sentence must bring some reference to the cold bath. While we believe the cold bath to be a most efficient adjunct in the treatment of the hyperpyrexia, we would at the same time urge that careful judgment be exercised in its employment. Given a patient with embarrassed peripheral circulation, with empty capillaries on the exposed surface, and the blood stagnant in the glandular viscera, one should hesitate in the use of an agent that admittedly favors the very condition to be combatted. The efficiency of the bath depends largely on the accompanying friction. In 75 per cent. of the cases here reported the cold bath was resorted to.

In all cases the routine treatment may be summed up as follows: The patient's temperature was taken; he was then placed in a low bath tub, in which the water was exactly of the same temperature; he was rubbed with large gritty sponges until redness of the skin was induced; this was followed by the turning on of the spray, the impact of which maintained the counter-irritation. After five or ten minutes the patient was removed from the bath and thoroughly rubbed with the sponges. If the temperature had not sufficiently subsided he was again placed in the bath and the process repeated until the temperature was reduced to the neighborhood of 100° F.; in the meantime he was given, either by the stomach or hypodermatically, $\frac{1}{30}$ of a grain of strychnine, $\frac{1}{40}$ of a grain of atropine, $\frac{1}{6}$ of a grain of morphine, and 20 drops of the tincture of digitalis, followed by a teaspoonful of aromatic spirit of ammonia in a glass of milk. The cases did well, and while we would not disparage the employment of the cold bath, we would insist that its efficiency must depend upon the energy of the friction, to secure a cutaneous afflux of blood.

In mild cases, in which the temperature was 101° F. or 102° F., from 5 to 10 grain doses of antipyrin or antifebrin relieved the headache, and usually the cramps, and reduced the temperature. We have not observed any unfavorable symptoms after the use of either of these drugs in properly selected cases. When we have used them we have usually accompanied their administration with applications of cold to the head, either by the ice cap or the cold spray, preferably the latter. The cold spray, if applied to the head and nape of the neck, will rapidly reduce the temperature, and time may be gained by using friction upon the back and upon the chest and extremities at the same time.

Alcoholic stimulants should be used in the large majority of cases. They favor increase of the peripheral circulation and invigorate the flagging heart. Blood-letting was resorted to in a single case, and upon the following indications: When brought into the accident-room the temperature of the patient was 103.6° F., and he presented no extraordinary symptoms. He was given $\frac{1}{60}$ of a grain of atropine, with $\frac{1}{6}$ of a grain of morphine. Friction was applied

to the chest and trunk; he was directed to lean over the bath-tub, and the cold spray was applied to the head, neck, and shoulders. The respiration became impeded; the man gasped for breath; the lips, ears, and finger-nails became blue, but not the general surface. Cheyne-Stokes breathing appeared. The man was bled to the extent of eight ounces, with immediate relief. He was sent to the Pennsylvania Hospital and returned to work on the following day.

The cold spray has in our hands been a most beneficial agent. The temperature of the water used varied from 40° F. to 55° F., but the force with which it was applied enhanced its usefulness, as the process practically amounted to active flagelation without inducing pain, and was promptly followed by redness.

As soon as active treatment was discontinued, or when practicable during its continuance, the patient was kept beneath the cool-air blast. One who has never seen the benefits of such a blast cannot appreciate its utility. Under active friction of the skin in the air-blast in many cases the temperature promptly subsided. The headache was invariably alleviated. The cool-air blast is, in our opinion, a most valuable adjunct. With it should be conjoined active friction, or if the patient is quiet, he should be in the recumbent posture, covered with a thin sheet, leaving the face free.

The regulation treatment in cases in which the temperature was subnormal (heat-exhaustion), consisted in the administration of stimulants, usually alcoholic, although hot drinks may with advantage be combined with alcohol. Rest in the recumbent posture is imperative.

It is probable that in the cases in which the temperature was practically normal the men were malingerers; but as they were few, they have not been separately considered.

SURGICAL DISEASES OF THE GALL-BLADDER AND GALL-DUCTS; WITH A REPORT OF FIVE CASES.

BY MILES F. PORTER, M.A., M.D.,[1]
PROFESSOR OF SURGERY AND CLINICAL SURGERY, MEDICAL DEPARTMENT TAYLOR UNIVERSITY, FORT WAYNE, IND.

CASE I.—Mr. R., seventy years old, German, a shoemaker, after suffering for about three years with marked jaundice, pain in the hepatic region, distention of the stomach and bowels with gas, and having nearly died from hemorrhage from a slight scalp-wound of the vertex received during this period, was placed in the hospital under the care of Dr. H. McCullough, who, with myself, regarded the case as one of malignant disease. The patient lived but a short time thereafter, and a *post-mortem* examination revealed the existence of inflammatory obliteration of the common duct, while the gall-bladder was closely contracted about a gall-stone, and was attached to the transverse colon, with which it communicated through a small opening. In the cystic duct was a second stone. The hepatic duct was patulous, so that some bile escaped through it and the remains of the gall-bladder into the large intestine.[1]

CASE II.—Mrs. P., fifty-two years old, a married woman, suffered for several years from what she termed "wind in the stomach," and was rubbing her abdomen to allay the pain during an attack, when she discovered a tumor, for which she consulted me. The tumor was not tender, but manipulation of it occasioned distress in the epigastric region. A diagnosis of gall-stones in the gall-bladder was made, and cholelithotomy was performed. From this the patient recovered. She is at the present writing in good health, but has a hernia at the site of the incision. She had for years also suffered from an anal fistula, and this was operated upon subsequently.[2]

CASE III.—Mrs. A., fifty years old, was seen by me, in consultation with Dr. H. McCullough, October 20, 1891. She gave a history of pain in the stomach, coming on at irregular intervals for several years, and accompanied by eructation of gas. She had never been jaundiced until the present illness. During the last illness she was unable to retain anything on the stomach. Examination showed the stomach to be somewhat distended with gas, which by pressure could be made to pass into the bowel, always with gurgling. No tumor could be detected. A diagnosis of obstruction at or near the pylorus and obstruction of the common bile-duct, due to an unknown cause, was made. Ten days after this visit the woman died. At the *post-mortem* examination the gall-bladder was found closely contracted about a calculus, and the common duct and duodenum, close to the pylorus, very much obstructed by adhesions resulting from a peritonitis of old standing.

CASE IV.—Mrs. S., fifty-four years old, the mother of five children, in 1865 began to have severe "dead" pain in the right hypochondrium, ceasing suddenly. These pains recurred at intervals of from two weeks to two years until 1885, when, after doing some hard work, she was rather suddenly seized with the same pain, which continued to trouble her at intervals for eighteen months, when it disappeared, and she grew fleshy and strong. In 1889 she commenced losing flesh, and complaining of pain in the same region, remittent in character, accompanied by pronounced jaundice and intense itching of the whole cutaneous surface. Soon after this last attack commenced, there developed pain and a tumor in the left hypochondriac region. The patient has suffered much from piles, and lately from prolapsus ani, and complains greatly

[1] Read before the Indiana State Medical Society, May 13, 1892.

[1] This case was reported and the specimens shown to the Fort Wayne Academy of Medicine.

[2] A report of this case will be found in the Transactions of the Indiana State Medical Society for 1889.

of distention of the stomach and bowels with gas. I saw her on January 15, 1892, when the foregoing history was obtained. She was much emaciated, deeply jaundiced, and had the expression of one who had suffered much.

On examination, the liver was found enlarged and hard; a tumor of the size and shape of the spleen, but rather harder, was detected in the left hypochondrium. A diagnosis of obstruction of the common or hepatic duct, probably by gall-stones, with enlargement of the liver and spleen, was made. The probability of malignancy was also entertained. Laparotomy was performed on February 20th, with the understanding that it might accomplish no more than the establishment of the diagnosis. The gall-bladder was found obliterated, and the hepatic or common duct bound to the posterior wall of the abdominal cavity, and containing three calculi, one of the size of a filbert, the others slightly smaller. The liver was slightly hobnailed in appearance, and hard. After trying to dislodge the calculi, and failing, the abdomen was closed. The case went on well until the morning of the fourth day, when the pulse became so weak that the nurse could not count it, and the patient complained of suffocation. At 2 P.M. on the same day I saw her, when the pulse was 147, the temperature 99.5° F., and the sense of suffocation less. Whiskey had been given, and I ordered nothing else. By 6 P.M. the pulse was down to 93, and all again went on well until the fifteenth day, when the woman complained of being cold; the pulse was 152, and weak. A hypodermatic injection of twelve drops of tincture of digitalis was given, with one-fiftieth grain of strychnine. The pulse soon fell to 80, and continued between that and 90 until the twenty-third day, when the patient went home. The strychnine was continued for several days after her return home.

The stitches were removed on the eighth day, the wound having healed perfectly. Up to April 12th the patient was improving; the stools were usually well-colored; there had been no itching since the first few days after the operation, unless she took morphine, which she has had to do for the pain, which still continues, though in less severe a degree. She now takes one-sixteenth of a grain of morphine twice daily, whereas before operation she took a quarter of a grain. The jaundice is still marked, though less decided since the operation. The greatest inconvenience results from gaseous distention of the bowels and stomach.

CASE V.—Mrs. D., a German, thirty-three years old, mother of two children, was referred to me by Dr. Carl Schilling. She commenced having cramps in the stomach eleven years ago; they were very severe, and would cease suddenly. They continued to trouble her for eight years, since which time she has had none, but has complained daily of severe burning pain, commencing in the right hypochondrium, and extending to the epigastrium and back. One year ago she first noticed a lump in her side. There is no clear history of jaundice, though the woman states that she has had "liver spots." Gas in the stomach and bowels has greatly distressed her during the whole of her illness. Examination revealed a freely movable tumor, apparently solid, in the region of the gall-bladder. A diagnosis of distention of the gall-bladder with gall-stones was made. Laparotomy was performed February 29, 1892. On opening the peritoneum, an elastic tumor was found; on introducing a trocar and canula, pus flowed freely. The gall-bladder was emptied, and explored with the finger and probe, but no stone was found. There were no adhesions. The bladder was stitched to the abdomen, and a rubber drain was left in. A sharp attack of peritonitis on the third day disappeared like magic under free catharsis from the use of salines. The stitches were removed on the eighth day, when the wound was healed, except where the drain had entered. The patient was allowed to get up on the fifteenth day, and left the hospital for her home on the twentieth day. The drain was removed on the twenty-third day. At no time was there more than the smallest quantity of pus in the discharge. At first this consisted of mucus, with very little bile, but subsequently it became clear bile, less profuse, and the woman expressed herself as well.

In three of the five cases here reported there was practically obliteration of the gall-bladder; that is, the viscus was so contracted, bound down, and changed, as to make it impossible to stitch it either to the abdominal wall or to the intestine. That this condition is of more frequent occurrence than we would be led to believe from the literature I feel sure, and it should be borne in mind in giving opinions in similar cases.

Kocher[1] performed a cholelithotripsy in a case in which the shrunken gall-bladder would not permit of the performance of the cholecystenterostomy.

Robson,[2] of Leeds, reports a case in which the gall-bladder was so far from the surface that he had to use the omentum to shut out the cavity of the peritoneum by first stitching the former to the gall-bladder, and then to the parietal peritoneum.

Shepherd,[3] of Montreal, used the liver and omentum for the same purpose in a similar case.

The use of contiguous tissues for the purpose indicated in the cases referred to offers hope in similar cases otherwise hopeless, and might have been applied in Case IV; but I feared that the woman would not withstand the shock of so prolonged an operation. Greater emphasis should be placed upon the diagnostic significance of the fermentation and consequent accumulation of gas in the stomach and bowels, together with pain and distress in the stomach. These phenomena also add evidence to the importance of the bile as an antiseptic. Piles and fistulæ, and rectal distress, are also of diagnostic significance. Of course, in Case III the gaseous

[3] Ibid., vol. xii, p. 333.

distention of the stomach was in part due to the mechanical obstruction.

While empyema and dropsy of the gall-bladder are usually due to gall-stones, they may be due to other causes, and may be susceptible of cure by cholecystotomy. H. C. Dalton [1] reports two cases of stricture of the gall-ducts due to inflammatory action from causes other than calculi.

Cases I and V further illustrate the difficulty of correct diagnosis.

Langenbuch,[2] who had performed twenty operations on the gall-bladder at the time, said: "Exploratory incision only will determine exactly with what kind of tumor we have to deal."

Tait[3] made a median section below the umbilicus for what he supposed to be a parovarian cyst, and found a distended gall-bladder.

Mears[4] made an exploratory incision in the lumbar region, in a case suspected to be one of floating kidney, but found a distended gall-bladder, with the cystic duct plugged by a calculus. His patient recovered.

West Hughes,[5] of Los Angeles, says: "So far as I can ascertain there have been only two other cases of non-adherent suppurating tumor of the gall-bladder successfully operated upon. There have been several such cases reported with fatal result, death being caused by suppurative peritonitis, due to the entrance of the contents of the gall-bladder into the peritoneal cavity. It would seem far better to operate in two stages, when this danger can be entirely eliminated." This danger of contamination of the peritoneum eliminated, there can be no doubt but that the completion of the operation at once is preferable. Careful sponge-packing will not always suffice. My experience leads me to believe that the contamination comes not so often from leakage at the side of the canula at the point of perforation, but from the pus that flows over the extremity of the instrument and down upon abdomen, hands, sponges, etc. This may be effectually prevented by first passing the trocar and canula through a piece of dentists' rubber dam of sufficient size. Then, with the hand grasping the instrument between the abdomen and rubber, trocar and canula are introduced; the trocar being removed by an assistant, the pus flows over the rubber, leaving sponges, hands, and wound clean. If thought advisable, the cavity can be washed out before removing the canula. Had this idea occurred to me years ago I might have saved my patients some discomfort and myself much worry.

[5] Ibid., vol. xii, p. 338.

In Case IV, as in a case of gastrostomy already published,[1] I believe the hypodermatic use of digitalis prevented death. I desire to urge the use of digitalis in this way, ofttimes advantageously combined with strychnine, not only after abdominal section, but in all cases in which death threatens from heart-failure.

In all, five cases are here reported: Four of gall-stones, and one of empyema of the gall-bladder; there was one death from obstruction of the duodenum, and one from cholemia; there were two cholecystotomies, one for stones and one for empyema, both cured. There was one incomplete operation, the case being somewhat benefitted, though still suffering, and threatening soon to die of cholemia.

47 W. WAYNE STREET.

CLINICAL MEMORANDA.

ALMOST TOTAL DESTRUCTION OF THE VELUM PALATI CORRECTED BY AN ARTIFICIAL SOFT PALATE, PRODUCING NOT ONLY GREATLY IMPROVED SPEECH, BUT AN IMMEDIATE INCREASE OF AUDITION.[2]

BY JAMES THORINGTON, M.D.,
OF PHILADELPHIA.

L. B., a girl, sixteen years old, born of English parents in Philadelphia, doing housework at home, was small in stature and features. The family history was good. Menstruation commenced a year ago, and has been normal and regular.

Her general health was good until July, 1884, when she contracted scarlet fever, followed two weeks later by diphtheria; she was confined to bed and to the house for the subsequent six months, on one occasion being considered beyond recovery. The patient states that her throat was the chief point of treatment, various washes, gargles, swabbings, etc., being used. No positive history of cauterization of the throat could be obtained. In one instance so much force was employed in making a throat-examination, with the handle of a spoon, that four loose (deciduous) teeth were knocked out, and the left commissure of the mouth was cut or lacerated for a distance of half an inch, leaving an irregular skin-scar.

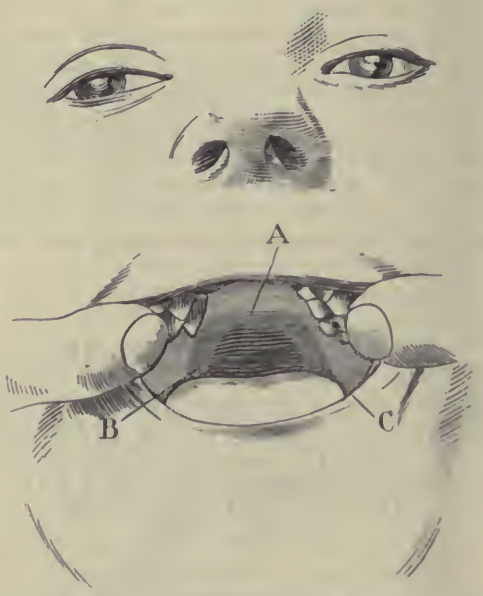
The patient's voice has a most marked nasal twang, and, while speaking, the alæ nasi can be plainly seen to open and close the nasal entrance. No history whatever of food or liquids at any time passing into the posterior nares and out through the nose could be obtained.

The patient is hard of hearing; she watches the speaker's lips carefully, and states that ever since the attack of scarlet fever there has been a constant discharge of a very offensive-smelling and light-colored pus

[1] Journal American Medical Association, vol. xi, p. 123.
[2] This case was presented at the Throat Clinic of the Jefferson Medical College Hospital, in January, 1892, and was placed under my care by Prof. J. Solis-Cohen, for treatment of the pathologic conditions and supplying the deficiency in the soft palate with an artificial appliance.

from both ears; the discharge is at times quite thick ("creamy"), and at other times watery in consistence. She has occasionally noticed that in the act of coughing, sneezing, or blowing the nose, air passes through and out of the ears. She has not had medical attendance or treatment since convalescence.

FIG. 1.



Mouth held open with index fingers.

A. Uvular band or cicatrix. B. Right palatine pillars, shown as one. C. Left palatine pillars, shown as one.

Looking into the open mouth (see Fig. 1, half the normal size), all of the permanent teeth are seen to be present, except the two upper cuspids, which are deciduous. The upper teeth are not regular in position. (See edges of the roof-plate, F, in Figs. 2 and 3.) The roof of the mouth is narrow and deep. The tongue appears normal. The fauces show complete absence of the uvula, and in its stead a broad (antero-posterior) cicatricial band, bright-red in color as compared with the surrounding pale tissues, extending across and connecting at the top the lateral pillars on each side. (A, in Fig. 1.) The lateral pillars—the right more particularly—are also broad cicatricial bands, and lie close together, almost as one, at their junction with, and for a short distance below, the uvular band, but may be separated with the end of a probe. (B and C, Fig. 1.) The tonsils are absent. In phonation no movement can be seen to take place in the right anterior pillar; the right posterior pillar acts slightly; the left pillars contract somewhat, as does also the uvular band, especially its left half. Digital examination proves the right anterior pillar to be a firm, unyielding cicatrix, without any indication whatever of muscular tissue. The left pillars, uvular band, and right posterior pillar, while composed of a great amount of cicatricial tissue, have some muscular fibers remaining.

The buccal pharynx—that part of the pharynx seen on looking into the widely-opened mouth—is one large, stellate, or spider-shaped cicatrix, having its body in the center of the buccal pharynx, and its many radiations or branches passing in as many directions. Viewing the post-nasal space with the mirror the left tensor palati muscle is seen to stand out prominently, as compared with its fellow of the opposite side, which consists of cicatricial tissue and has but slight muscular action; as a result, the entrance to the post-nasal space from below is of irregular shape. (K, in Fig. 2.) The various parts, as seen in the post-nasal space—septum, turbinates, entrance to Eustachian tubes, etc.—present no abnormality, except a chronic thickening of the mucous membrane; the otherwise normal condition of the Eustachian tubes having an important bearing on the result of the treatment, as will hereafter be explained. The larynx presented no abnormality.

The auditory auricles are normal; the auditory canals, after the removal of the accumulated pus, were found narrow, deep, and macerated, but, owing to sensitiveness or fear on the part of the patient, it was impossible to obtain a satisfactory view of the membranes or ossicles. Air was forced through the ears. Hearing by the watch was: Right, 5 inches; left, 4 inches.

The treatment resolved itself into three parts: First, for the post-nasal and pharyngeal changes; second, for the otorrhea; and, third, the procuring, for the relief of the altered condition of the parts, of an artificial appliance that would improve speech and, possibly, hearing. The parts being so contracted and muscular tissue scarce, the idea of surgical interference was not entertained.

The patient being in apparently good health, there was no indication for constitutional treatment, and none was given. In consultation with a dentist it was considered possible (though not definitely promised) to make a velum that would assist the patient's speech and, perchance, the audition; this possibility being based on the assistance that it was hoped or anticipated could be obtained from the muscular fibers in the right posterior and left pillars, so as to act on the artificial velum. While this velum was being made, attention was given to the treatment of the throat and ears. For the former, alkaline washes of various strengths were used to keep the parts clean and free from the thick, tenacious mucus that would otherwise accumulate. Under this treatment the secretion diminished in quantity and in tenacity, and with occasional applications of a weak iodine-solution the thickening of the membranes was much reduced.

The auditory canals were kept clean by means of a weak solution of hydrogen dioxide, dried with absorbent cotton, and daily insufflations of boric acid. After a few days of this treatment the discharge lost its offensive odor, and at the end of nine weeks there was a cessation of the discharge from the right ear, and in the left at the end of twelve weeks. Cerumen appeared at about this time, the first noticed since the attack of scarlet fever. A watch could now be heard with the right ear at 7 inches; with the left at 7 inches. Each ear showed absence of drum-membrane and ossicles. The promontory could be seen, and the foot of the stirrup resting on the oval window.

Figs. 2, 3, and 4 show the upper, under, and right lateral surfaces, respectively, of the artificial palate, one-half the natural size. F, in each figure, is the roof-plate, or the plate that fits to the roof of the mouth; it is composed of vulcanized rubber, and is exactly the same kind of a plate that is used for an upper set of false teeth. G G, in Figs. 2 and 3, are gold clamps that fasten

round the first molar teeth, to hold the roof-plate F *in situ*. I, in Fig. 3, is the fastened end of a narrow piece of gold that runs backward through the substance of the roof-

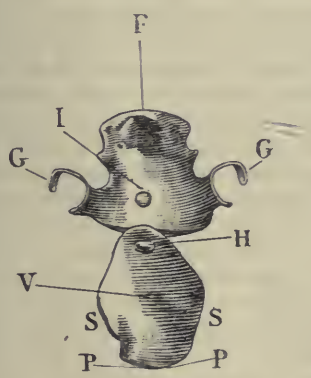
F. Roof-plate. GG. Gold bands. H. Upper part of gold stud (*vide* H, in Fig. 3). K. Heel of velum. P, P. Posterior or pharyngeal margin of velum. S, S. Lateral or arch surfaces of velum.

plate to H, Figs. 2 and 3, where it is broadened out into a stud, which holds the velum V, Figs. 2, 3, and 4.

The velum is composed of soft red rubber, is very pliable, and takes its original shape as soon as the pressure is removed. K, Figs. 2 and 4, is a (hollow) prominence, or heel, which fits into the naso-pharyngeal

FIG. 3.



Under surface of artificial palate.

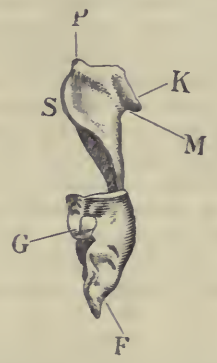
I. Fastening of gold band that passes to form the stud H (Figs. 2 and 3). (Other letters have the same references as in Fig. 2.)

space. M, in Fig. 4, shows the anterior part of the heel, which approximates the back of the uvular band, but does not exert any pressure of itself, though just near enough to receive pressure at the time of muscular contraction. The upper margin of the heel, when in position, will be just below the floor of the nares. The irregular shape of the front of the heel will be noticed in Fig. 2.

Placing this unique piece of workmanship *in situ*, it will be understood from the description given that, the velum being in repose, the edges marked S and S lie accurately against the palatine arches, and that the posterior or pharyngeal margin, P P, Figs. 2, 3, and 4, stands out or hangs away from the pharyngeal wall, leaving a space of less than two-eighths of an inch, which is quite sufficient to allow of free respiration through the nares, and for thin secretions to pass down from above.

When the patient phonates with mouth wide open, the left arch and tensor palati contract at S, Fig. 2, and force the velum up and back; at the same time the pharynx contracts, comes forward and meets the velum at P P, thus completely closing the nasal passage, and directing the voice forward through the mouth, the artificial velum acting the part or taking the place of the natural velum in opening and closing the nasal passage, as required in talking or swallowing.

FIG. 4.



M. Anterior aspect of heel. K. Right side view of artificial palate.

(Other letters have the same references as in Figs. 2 and 3.)

As for the velum itself, much is to be said in its favor The danger of it becoming detached and swallowed is almost *nil*, when it is observed how securely it is held in position by the stud H, Figs. 2 and 3. Owing to the size of the velum, in comparison with the smaller size of the laryngeal opening, it would be impossible for it to take that course, should it become detached. The risk of irritating the parts with which it comes in contact was carefully considered, and for this reason the soft rubber velum was first made; and as there has been no inflammation or unpleasantness following its use, a hard rubber velum is now in process of construction. One important reason, perchance, that the velum has not irritated the fauces is on account of the insensitive cicatricial condition of the parts.

Secretions accumulate on its upper surface, especially if thick, and, as a consequence, there is a reduction in audition, no doubt from pressure, or plugging of the Eustachian tubes. This is the only inconvenience resulting from the use of the velum, but one that the patient can, and does, easily remedy by removing and cleansing the velum and the parts. There is no difficulty in this; the patient passes the index-fingers to G G, Fig. 2, and, pulling downward on the gold clasps, the plate falls, is lifted from the mouth and cleansed in tepid water; it is easily and securely re-inserted by passing it well back and bringing the gold clasps to the edge of the first molars and pressing upward.

The velum has been made as light and thin as possible, and accurately approximates the buccal pharynx

when in action. Were it permissible to allow more space than the present two-eighths of an inch between its posterior edge and the buccal pharynx when in repose there would not be so much, if any, retained secretion, but this cannot be accomplished without leaving an opening into the nasal passage during the action of the velum, and thus neutralize the use for which it is intended. It is hoped that with the use of the velum the mucous membrane may continue to improve and the secretion remain thin enough to flow freely at all times through the space allowed, and by the aid of nasal inspiration the patient be able to draw the mucus into the throat. By reason of the retained secretion the patient is not allowed to wear the velum during sleep.

Two mechanisms being required in speech—the laryngeal and oral (the vibrator and resonator)—and normal speech requiring perfect coördination of the two, the velum in this case, by supplying the previous vacancy, gives almost perfect resonance as the result, and does away with most of the former nasal twang. This twang will further diminish and gradually pass away as the patient overcomes her habit of closing the nostrils with the alæ nasi. Prior to the use of the velum, in pronouncing words containing a *c* or *s* followed by a vowel, there was a marked *th*-sound, but this is rapidly leaving, and is now almost gone. Six was pronounced "thix"; seven, "theven"; sound, "thound"; Susie, "Thuthie"; cider, "thider"; Cincinnati, "Thinthinnati," etc.

The improvement in hearing that has resulted from the use of the velum is an advantage that equals, if it does not exceed, the bettered speech. As the title of this article states, the improvement in audition was immediate (R. and L. = 20 inches), and has increased gradually until at the time of writing, six weeks from the first use of the velum, the hearing for the watch has reached, right and left, 31 inches. As soon as the velum is removed, the audition for the watch falls to, right and left, 7 inches, showing that the improvement is most likely mechanical—*i. e.*, from the support given to the Eustachian tubes. Had the entrances to the tubes suffered from ulceration, as did the other tissues, it is not likely that the velum would have improved audition.

With this improved audition and speech the patient becomes a better and happier member of society, and now enjoys her surroundings and associates with greater satisfaction than at any time since her recovery from the scarlet fever. Prof. Cohen, who has just examined the case, pronounces it the most successful result he has ever witnessed in such extensive devastation of tissue.

1630 ARCH STREET.

ANEURISM OF THE AORTA IN A CHILD OF FOUR AND A HALF YEARS.

BY R. A. H. MACKEEN, M.D.,
OF COW BAY, CAPE BRETON.

IN the summer of 1889 I was called to see M. M., a little girl, four years and nine months old. Her mother stated that since the preceding spring the child had been troubled with a continuous, hacking cough, for which various remedies had been tried without avail. The child had failed somewhat in strength and suffered from shortness of breath. Otherwise she was able to play with her companions as usual. The family history was good. She had never suffered from severe illness, but in the previous winter, while running, she had fallen, striking her breast heavily upon the doorstep. Beyond a feeling of soreness, this accident did not occasion any inconvenience at the time.

Examination of the chest. Inspection showed a pulsating swelling in the first intercostal space just to the left of the upper extremity of the sternum. The pulsation was distinctly expansile, with a slight thrill, most distinct at the lower and outer part of the tumor. The breathing in the left lung was free and not interfered with, except over the surface of the tumor, where there was absence of respiratory murmur. In this region a systolic murmur could be heard. The left radial pulse was somewhat behind the right in time. The voice was not interfered with. A diagnosis of aneurism of the aorta was made.

The only explanation of non-involvement of the left laryngeal nerve would be that the aneurism must have arisen on the left side of the ascending part of the aorta and below the point at which the nerve crosses the vessels. Judging from its situation, it is not probable that the aneurism had any connection with the ductus arteriosus. The patient was afterward examined at my request by Dr. Wm. McKay, who agreed in the diagnosis. In the following summer I had the opportunity of showing the case to Dr. McPhedran, Associate Professor of Medicine in the University of Toronto, who, after a very careful examination, agreed with the previous opinion.

At the beginning of the next winter the patient was seized with a rigor and pain in the right side. There were coldness of the skin and great depression. Reaction did not set in for twenty-four hours, when there was elevation of temperature, accompanied by rusty expectoration. Pneumonia had developed in the upper lobe of the right lung. Though the crisis was apparently reached in due time, the lung did not close up, and soon underwent degeneration. Death resulted in the course of two months. It is to be regretted that no autopsy could be obtained.

It is safe to assume that at the most the patient could not have been more than four years and three months old when the aneurism developed, and her extreme youth lends special interest to the case. Henoch, with his large experience, never saw an aneurism in so young a child. Two cases were recently reported in the *British Medical Journal*—one in a patient three years old, and the other in a child four years old.

MEDICAL PROGRESS.

Cerebral Surgery.—HITZIG (*Berliner klin. Wochenschrift*, 1892, No. 29, p. 713) has reported the case of a mason, twenty-nine years old, who, following a blow in the right frontal region, complained of pain at the site of injury, with impairment of memory, defective intelligence, and attacks in which paresis of the left hand appeared, while the mouth was drawn to the left; speech and deglutition were likewise slightly affected. Subsequently, vision became impaired upon the right, and then upon the left. There had been no vomiting; and there was no alteration of the pulse. The head was bent

strongly forward and slightly to the left; the left shoulder drooped somewhat. There was bilateral papillitis and concentric limitation of the visual fields. The muscles of the right side of the face were paretic. The tongue was protruded a little to the right. There was also loss of power in the left upper extremity. There was some weakness of lower extremities, slightly the greater upon the left side. Sensibility was not deranged. The knee-jerks were exaggerated, the left in greater degree than the right. Ankle-clonus was present upon the left, and the skin-reflexes were exaggerated. In the right temporal region, in a situation corresponding with the anterior half of the origin of the temporal muscle, was a doughy tumefaction, painful upon pressure. A diagnosis of a tumor of the bone exerting pressure upon the brain in the temporal region was made, and operative procedure decided upon. A large extent of bone was removed in the right temporo-parietal region, leaving an opening in the skull of about 3½ by 4¼ inches. The bone in places was thin; in others, thickened. A large growth was found arising from the brain and penetrating the dura. The neoplasm was carefully removed. It weighed nearly nine ounces, and proved to be a mixed sarcoma. The patient recovered absolutely from the operation, without noteworthy aggravation of his previous paretic condition.

Carcinoma of the Cecum.—As the result of a careful study, MATLAKOWSKI (*Deutsche Zeitschrift f. Chirurgie*, Bd. xxxiii, H. 4 u. 5, 321) concludes that carcinoma of the cecum is not rarely a most chronic condition that may exist for years without giving rise to symptoms other than slight constipation and the presence of a tumor. The prognosis of operation at this stage would be most favorable. Resection, with immediate enterorrhaphy, is the ideal operation. If the patient come under observation with symptoms of intestinal obstruction, neither resection nor intestinal anastomosis is to be undertaken, but an artificial anus is to be established in the small intestine as near as possible to the ileo-cecal valve. When the patient has regained strength, resection and enterorrhaphy may be performed or an anastomosis established. An artificial anus should never be established after resection of the cecum has been performed, except in case of obstruction; instead, an enterorrhaphy should be performed; or, if this be impossible, an anastomosis should be established. If resection is impossible, or seems contra-indicated by the debilitated condition of the patient, an anastomosis should be established. If the carcinomatous disease be circumscribed and not generalized or disseminated, and resection and enterorrhaphy or anastomosis in one sitting appears too tedious or too dangerous, enterorrhaphy or anastomosis, excluding the tumor from the abdominal cavity, may be first performed, and as the condition of the patient improves, the growth may be extirpated. In favorable cases resection of the carcinomatous cecum and primary enterorrhaphy may be followed by curative results, lasting for years, as indicated by the general condition of the patient and the functional activity of the bowel.

Eclampsia.—OLSHAUSEN (*Sammlung d. klin. Vorträge*, No. 39, 1892) considers eclampsia an intoxication, dependent upon interference with the function of the kidneys, usually acute. There is most frequently an acute or subacute change in the parenchyma of the kidney, less commonly chronic nephritis, with acute fatty degeneration. Exceptionally, such conditions as compression of the ureter or intoxication by corrosive sublimate or carbolic acid are present. If the eclamptic attack cease without interrupting the pregnancy, the convulsions are almost never repeated at the time of birth. It has not been determined whether or not this is dependent upon the death of the child. The prognosis is governed by the possibility of speedily terminating the labor and by the number and violence of the attacks. A poor pulse and a high temperature are of unfavorable prognosis. True puerperal eclampsia, setting in soon after labor, is less dangerous than eclampsia setting in late. Attacks are sometimes preceded by auræ, consciousness not being entirely lost. Albuminuria is rarely absent. Morphine, in large doses, is indicated; but if contra-indicated by small pulse and contracted pupils, chloral should be given by enema. In the case of a multipara, the amnial sac is to be ruptured as early as possible, to induce or to inaugurate labor. As soon as the cervix offers no obstruction, the forceps is to be applied. Version and incision of the cervix are to be sparingly employed. In an exceptional case, in the interest of the mother, or, if the parent be moribund, in the interest of the child, Cæsarean section may be indicated.—*Centralblatt für die gesammte Therapie*, 1892, x, 7, p. 426.

Gastrostomy for Stricture of the Esophagus in a Child of Four.—At a meeting of the Clinical Society of London, CHITTON (*Lancet*, 1892, 3588, p. 1244) reported the case of a girl, four years old, who, when seen, seven weeks after swallowing some caustic soda, was unable to swallow anything, while a bougie was arrested at a point six inches from the teeth. To secure absolute rest for the esophagus, the little patient was fed by nutrient enemata. At the expiration of two months, as no instrument could yet be passed, the esophagus was opened in the neck, in the hope of reaching the stricture. The obstruction was found, however, to be within the thorax. The wound was closed, and the first stage of gastrostomy undertaken by means of hare-lip pins. Five days later, the stomach was opened and the child was fed through the gastric fistula. After the lapse of five months, a small bougie was made to pass through the stricture, and after many months of varying success a No. 14 esophageal bougie was passed with ease. In the following year, this large bougie was passed about once a month, and the plug removed from the gastric opening, which was gradually made to close by application of the actual cautery. The girl was ultimately restored to perfect health, presenting herself every six weeks to have the bougie passed.

Sudden Death from the Presence of a Spool-worm in the Trachea.—HEUSSER (*Corresp.-bl. f. Schweizer Aerzte*, No. 14, p. 443) reports the case of a boy, eight years old, to whom he was hurriedly called on account of interference with respiration of sudden onset and for which no cause was evident. Death took place, and the autopsy revealed the presence of a spool-worm at the bifurcation of the trachea, and projecting for some

distance into one of the bronchi. The assumption is that the worm found its way into the pharynx, and thence was aspirated into the trachea.

The Renal Function in the Fetus.—RISSMAN (*Centralbl. f. Gynäkol.*, 1892, No. 26, p. 497) has reported the case of a unipara who gave birth to an eight months' male fetus that presented pes equinus and bilateral cryptorchismus. The child, which lived for four and a half hours, was in other respects well-developed, but there was entire absence of the kidneys and ureters. The bladder was small and presented a depression indicative of the point at which the ureter should have entered. Both testicles, with their adnexæ, lay in the false pelvis.

Unilateral Syringomyelia.—At a meeting of the French Society of Biology, DÉJERINE (*La Méd. Moderne*, No. 30, p. 489) reported the case of a man, fifty-five years old, who presented the symptoms of syringomyelia, confined, however, to one side of the body. The patient died of pneumonia, and the autopsy disclosed the existence of a gliomatous cavity involving the right side of the cord from the cervical region to the lumbar enlargement, with its maximum of development at the cervical enlargement.

Disorders of Speech in Paralysis Agitans.—ROSENBERG (*Berliner klin. Wochenschr.*, No. 31, 1892, p. 771) has reported a case of paralysis agitans in a man, sixty-two years old, in whom the disease had existed for thirty years, and who presented disturbances of both articulation and phonation, dependent on participation in the tremor of the muscles of the lips, cheeks, tongue, and palate, as well as of the vocal bands.

The Detection of Tubercle-bacilli in Sputum.—KAUFMANN (*Centralbl. f. Bakteriol. u. Parasitenk.*, Bd. xii, No. 4 u. 5, p. 142) has found that tubercle-bacilli contained in sputum spread upon cover-glasses, fixed and stained in the usual way, are not decolorized by exposure to boiling water for from one and a half to three minutes, while most other bacteria lose their color.

THERAPEUTIC NOTES.

Paraldehyde as a Diuretic.—In a case of senile arterial degeneration, with mental depression, restlessness, insomnia, and valvular disease of the heart, other hypnotics failing, SYSON (*Lancet*, No. 3595, p. 195) employed paraldehyde, both in full medicinal doses and in small doses repeated at short intervals. Restlessness and sleeplessness were in a satisfactory degree controlled; in addition, a distinct diuretic effect was observed, intercurrent dropsy being relieved.

For Hemorrhoids.—

℞.—Morphinæ . . . . . gr. v.
Hydrarg. chlor. mit. . . . ʒj.
Glycerin. . . . . ʒiv.
Bismuth subnitrat. } . . āā ʒjss.
Vaselin. }
M. et ft. unguent.
S.—Apply topically. ALLINGHAM.

Hydrastis Canadensis for the Vomiting of Pregnancy.—FÉRODOW, a Russian gynecologist, has controlled obstinate vomiting in four cases of pregnancy by the administration of twenty drops of fluid extract of hydrastis four times a day. The efficacy of the remedy is said to depend upon a lowering of the blood-pressure, relieving the engorgement of the uterus, and upon a sedative influence upon the motor nervous centers and the gastro-intestinal canal.—*Gazette Méd. de Paris; Lyon Médical*, No. 31, p. 483.

For Hay-fever.—

℞.—Morphinæ sulphat. . . . gr. ss.
Cocaine hydrochlor. . . . gr. j.
Menthol. . . . . gr. iij.
Bismuthi carbonat. . . . gr. viij.
M. et ft. pulv.
S. Use as a snuff.
WELFORD, *Canadian Practitioner.*

The Removal of Deposits of Pigment in the Skin.—GÖNNER (*Correspondenzbl. f. Schweiz. Aertze*, No. 14, p. 462) states that pigment-hypertrophies can be removed by applying, at bedtime, a thin layer of soft soap, which is removed in the morning. In the course of a few days the skin peels off, and the deposit of pigment has disappeared. If pain and redness occasion distress, borated or salicylated vaselin may be applied.

For Dysentery.—

℞.—Morphinæ sulphat. . . . gr. j.
Magnesii sulphat. . . . . ʒj.
Acid. sulphuric. dil. . . . fʒij.
Aquæ . . . . . fʒiv.—M.
S. A tablespoonful every three hours.
BARTHOLOW.

The Treatment of Rabies.—TIZZONI and CENTANNI (*Deutsche medicin. Wochenschr.*, No. 31, p. 702) have, by precipitation with alcohol, been able to obtain from the blood-serum of animals rendered immune to rabies, a body that, dissolved in water, is also capable not only of conferring immunity, but also of effecting a cure when the disease is already developed.

For Itching.—

℞.—Menthol. . . . . gr. xij.
Alcohol. . . . . ʒjss.
Aquæ . . . . . ʒiij.
Acid. acetic. . . . . ʒj.—M.
S. Apply by means of a sponge.
—*Rev. de Thér. et Méd.-chir.*

For Gonorrhea.—MANGANOTTI recommends from three to five injections daily of from a three to a five per cent. solution of ichthyol in the treatment of gonorrhea.—*Correspondenzbl. f. Schweiz. Aerzte.*

For Fissured Nipples.—It is recommended that egg-albumen be applied to fissured nipples after nursing, and be permitted to dry, and be again moistened before the child is put to the breast.—VAN ALLEN.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

PHILADELPHIA.

SATURDAY, SEPTEMBER 3, 1892.

CHOLERA.

IT cannot be doubted that the present danger of a visitation of cholera to this country is greater than has existed for many years. The most recent reports may be exaggerated, and some deductions must surely be made for the extremely hot weather that has prevailed in western Europe; but the existence of the disease in three of the most important ports for passenger-embarkation places this country in far more direct communication than if the epidemic were limited to eastern or southeastern Europe.

All of the methods of transmission of the disease are not known, but it seems certain that persons and personal effects of immigrants from infected localities are likely to convey it. No evidence is at hand to indicate that ordinary merchandise is dangerous. The iron ore, chalk, clay, glassware, and other articles that we receive from Europe cannot be suspected. Even baled old rags, which have been so much condemned, have never been known to convey the contagion, although the opinions of some sanitary authorities have led to a different view among the people.

In an epidemic of this character, the quarantine-service of the various ports is naturally looked to for protection. On every occasion of the appearance of the disease in Europe, an overhauling of these coast-defences has been made, and much occupation has been given to the newspaper reporter in the description of the appliances for inspection and disinfection. Since the outbreak of the last epidemic in this country, about twenty-five years ago, a vast advance has been made in the knowledge of contagious diseases and in the efficiency of disinfectants. Inventive genius has supplemented theoretic knowledge, and apparatus, rapid, efficient, and economic, is now available. The application of steam in a closed space seems to be the best method that will accomplish disinfection with the least injury to the articles, a point that should by no means be left out of consideration.

The health authorities of the Atlantic seaboard are mostly well prepared to deal with the emergency, and while in some ports the facilities for handling and discharging baggage are such that considerable delay will occur, this will not impair the efficiency of the work. Fortunately, cholera is a disease of a characteristic nature, so that actual cases cannot escape detection.

If we except the advantage gained by a more accurate knowledge of the value of special disinfectants, it must be confessed that as regards the limitation of cholera epidemics we are to-day not in much better position than in former visitations. Isolation, general sanitary precautions, disinfection of clothing and discharges will be the principal means to be employed. Intelligent communities will not be likely to rely on tar oils or the aromatic disinfectants, but will employ those that are known to be efficient; and in this connection it may be well to point out that experiment has shown the value of slaked lime as a germicide, and that even strong brine has considerable effect. The former may be used freely, without danger, and is cheap and easily applied. It will probably be of service in the disinfection of discharges.

Without entering on the still somewhat disputed question of the causal relation of the so-called comma bacillus, it may be affirmed that drinking-water is an easy and frequent channel for the extension of a local epidemic, and that in many American cities so little attention has been paid to protecting streams from sewage-pollution, or providing means for the purification of such sources of supply, that serious danger arises from the possibility of introduction of the germs at the upper points on streams

and their subsequent entrance into the water-supply at places further down.

The contamination of the milk-supply is also a danger. The sterilization of all milk is a duty in every household, more especially as this, so far as the comma-bacillus is concerned, is easily brought about. This organism is one of the most sensitive known. According to FRAENKEL, it is killed by temperatures above 120° F. It perishes quickly when dried, and also when associated with large numbers of ordinary water bacteria. To this region and climate it is essentially an exotic plant, and it would seem not difficult to restrict its admission and extension within narrow limits.

We may expect that in the excitement of the moment some unnecessary steps will be taken and some injustice done to commerce and trade, but the medical and sanitary knowledge and methods of the people of the United States will doubtless be found fully able to prevent any serious result.

PROGRESS AND REGRESS IN MATERIA MEDICA.

THE distinct and clearly defined danger that the medical profession runs from the persistent influence of commercial manufacturers of secret preparations is exactly analogized by the pernicious influence of the "patent medicine" syndicates in the drug-business. THE MEDICAL NEWS is clearly of the opinion that the non-medical manufacturer or discoverer of a new drug or therapeutic agent may legitimately patent his discovery, but may not copyright the name only, while keeping the constitution and method of preparation of the article secret. In this manner he will have a proper reward for his energy and outlay of capital. As a profession we allow this right to the unprofessional discoverer, but demand of our own members a still higher standard of morality, in tha we do not permit any physician either to patent a discovery or copyright the name of a proprietary article. This professional magnanimity to others, whilst strictly denying it to ourselves, is a clear evidence of our freedom from dogmatism or hobby-riding.

The profession, however, has a clear duty to perform as regards the action of manufacturers of secret preparations.[1] One by one these men, by fair means or foul, are getting greater and greater control of members of the profession, convincing them by arguments, good, bad, selfish, or corrupt, of the especial excellence of certain products, and dulling the sense of professional honor in making them overlook the fact that these preparations, however cunningly the fact is sought to be hidden, are secret nostrums. Some of these nostrums are, perhaps, excellent preparations, but the secrecy of their origin, nature, or method of preparation throws them out of the armamentarium of the honorable physician, because the physician must have knowledge of what he is using, and guarantees, through his ability to test the preparation, that its composition will always remain identical.

The U. S. Pharmacopeia will not admit secret preparations, because the very purpose of the Pharmacopeia is to establish a standard of strength and purity, and obviously there can be no standard when secrecy is permitted. Pharmacists and physicians thus unite in condemning secrecy concerning medicinal preparations for the reasons given, and in addition because of the fact that only by secrecy can worthless and vicious compounds be pushed upon us.

One by one medical journals have given way under the threat or the bribe of valuable advertisements, or of special orders for thousands of an issue containing an article, and in many of the best and all of the worst there constantly appear articles in praise of these preparations, and in almost none are there manly and frank condemnation of these things. It remains for the medical profession to clearly determine whether it shall have independent and truly professional journals, or whether they shall be the secret or half-secret slaves of the manufacturers of secret preparations.

We are glad to know that this position of THE MEDICAL NEWS is that unanimously endorsed by the PHILADELPHIA COUNTY MEDICAL SOCIETY, the PENNSYLVANIA STATE MEDICAL SOCIETY, the MISSOURI STATE MEDICAL SOCIETY, the AMERICAN MEDICAL ASSOCIATION, and the AMERICAN PHARMACEUTICAL ASSOCIATION.

One thing is clear. It is not necessary to make secret preparations in order to make money; it is not necessary to fly in the face of medical tradition and medical honor to succeed in a purely commercial sense in the pharmaceutical business. This has been demonstrated by the conduct of a number of firms. Moreover, such firms as these conceive it to be good policy as well as duty to aid the medical

[1] A secret preparation is one "of which no working formula is or will be published."

profession instead of coercing it. When a firm, while refusing to make secret preparations, has the largeness of character and nobility of purpose to spend money like water to push original pharmacologic investigations into new fields, to buy splendid books, issue good periodicals, outfit research laboratories, publish exhaustive and expensive works, bulletins, and reports, the weary physician will turn with gladness to such men as his friends rather than to those who, doing nothing for the work of his life, seek to make him a commercial sales-agent for products of unknown constitution.

REVIEWS.

PRACTICAL MEDICAL THERAPY: A BOOK FOR THE FAMILY, THE PHYSICIAN, AND THE DRUGGIST. A POPULAR TREATISE ON THE PREVENTION AND CURE OF DISEASES, AND THE USE AND ABUSE OF MEDICINES. Embracing the Essential Principles of Medical Practice in Accord with the Latest Scientific Research and the Most Advanced Medical Treatment; Setting Forth the Correct and Intrinsic Values of Drugs and Medicines as Curative Agents, and Telling How to Save Life, Health, Time, and Money in their Use; to Which is Added a Great Variety of Valuable Formulas for Medicinal, Toilet and Household Purposes, Receipts for Disinfectants, Insecticides, Hygienic Measures, etc. By JOSEPH A. CONWELL, M.D., Physician and Druggist. Sold by subscription only. Vineland, N. J.: The Conwell Publishing Co., 1892.

THIS book contains so much that is good, pertinent, timely, that it is with profound regret that we find ourselves compelled to say that it contains likewise much that is not good, not pertinent, not timely. Repelled by the pompous pretentiousness of the title-page, we were delightfully surprised to find, in Part I, a series of well-written, concise, sensible essays upon the place and scope of medicine, the merits and demerits of the "pathies," the relations and reciprocal duties of the family physician and his patients, the functions of specialism and specialists, the nature of worthy and unworthy medical practice, the schemes and methods of medical frauds, patent and secret medicines, quack-doctors, and the like. Chapters on unnecessary medicine, imaginary diseases, and popular errors, likewise deserve special commendatory mention. We wish the author had here written Finis, or that he would print a special edition, consisting of this part of the book and the household recipes only. We would then advise physicians generally to see that their patients bought the book. It would do good. Part II gives concise statements concerning "the nature, cause, symptoms, prevention, and cure" of various disorders, arranged alphabetically. These brief statements are of slight value to the physician, and while a few contain useful directions for emergencies, as a whole, this part of the work can only do harm to the lay reader who may attempt to act on its direction, without medical advice. It contains a few lamentable misstatements, such as that concerning tracheotomy in croup, which may be prejudicial. Had the articles been confined to the proper hygienic and prophylactic measures to be adopted under certain circumstances, Part II might have been worthy of Part I, but these matters are not given with anything like sufficient fulness. We trust the author will rewrite the articles from a purely popular standpoint. He has failed only because he has attempted the impossible—to combine popular and technical treatment of his theme in one article. Part III, on Materia Medica and Therapeutics, is more useful, and might, with a little alteration, be allowed to stand for popular information in a new edition. We repeat our regret upon the necessity of making any unfavorable comment upon this book.

We have only commendation for the spirit in which the work has been undertaken, for the lucidity and brevity of its style, and for the matter of that part of it properly belonging in a popular treatise. We doubt not the author has the knowledge and ability to write an acceptable compendium of practice for physicians, but this should be a separate work.

THE WIFE AND MOTHER: A MEDICAL GUIDE TO THE CARE OF HER HEALTH AND THE MANAGEMENT OF HER CHILDREN. By ALBERT WESTLAND, M.A., M.D., C.M. 8vo, pp. xiv, 282. Philadelphia: P. Blakiston, Son & Co., 1892.

A NOTICEABLE point about this little volume is the commendable absence of technical terms, as the author plainly states that it is for the use of "women who are desirous of fulfilling their proper duties of wives and mothers." Too often, in works of this class, the readers for whom they are intended are confused and led astray by the multiplicity of words and phrases meant rather for the practitioner than for the mother.

The book is divided into four parts. The first part treats largely of pregnancy and its complications, and gives some sound advice to those about to marry; it *explains* in a lucid manner the symptoms of approaching motherhood. Several chapters are devoted to parturition and its concomitants.

The second part considers the puerperal state and the relations of mother and infant. The third part takes up the greatest portion of the volume. The care of the child during early infancy is intelligently and fully considered, together with the ills to which it is liable. This part of the work, however, would be the better for a properly-arranged diet-list for the child after it has ceased taking nourishment from the mother.

Part four deals with the menopause. There is an appendix, containing the law relating to registration of births in the United Kingdom, the law relating to vaccination of children, and the law relating to notification of infectious diseases, and there is a well-arranged index.

Altogether the book fulfils the objects for which it was written, and will materially assist the young married woman in the intelligent performance of her new duties.

The Tri-State Medical Association of Alabama, Georgia, and Tennessee will hold its fourth annual meeting at Chattanooga, October 25, 26, and 27, 1892. Quite an interesting scientific program has been arranged.

CORRESPONDENCE.

SOUND AS A THERAPEUTIC AGENT IN DEAFNESS AND TINNITUS AURIUM.

To the Editor of THE MEDICAL NEWS,

SIR: "The man that once did sell the lion's skin while the beast lived, was killed with hunting him."

The attention of the profession was called to the beginning of my labors in the employment of sound as a therapeutic agent in papers presented to the College of Physicians of Philadelphia, April 6, 1887, and to the American Otological Society at its meeting, New London, Conn., July 19, 1887, and by publications as follows: "The Sphenoid Bone; Some of its Possible Functions," *New York Medical Journal*, August 11, 1888; "A Study in Physiological Acoustics: Preliminary Notice," *New York Medical Record*, November 17, 1888; a presentation of results in typical cases entitled, "Otacoustic Treatment in Chronic Deafness," *Annals of Opthalmology and Otology*, January, 1892.

During the month of November, 1891, there appeared at times articles in the lay press entitled "New Way to Cure Deafness;" "Sound Waves in the Treatment of Aural Diseases," by Henry F. Garey, Professor of Otology in the Southern Homeopathic College, Baltimore, Md. The ambiguous phrasing of said publications I considered an injustice to me for two reasons:

1st. That Garey came to Washington on December 17, 1890, with F. C. Drane, dean of said college, to be treated by me.

2d. He had applied *similia similibus curantur* to sound, and with this only and a knowledge derived from me, attempted to deceive the public through said publications by attempting to pose as the discoverer of sound as a therapeutic agent in deafness and tinnitus aurium.

I therefore addressed to the faculty of said college through its registrar a protest against this assumption of Garey, and received a reply substantially sustaining Garey, whereupon I issued a pamphlet giving all the facts, and addressed a copy to each member of The Institute of Homeopathy at their meeting, Washington, D. C., June 13, 1892. No notice was taken of my protests against Garey's attempts at deception, although Garey in his address before that body on "Massage of the Sound-conducting Apparatus of the Ear," said, "Massage of the sound-conducting apparatus of the ear has been used by me experimentally ever since the opening of the clinics at the Southern Homeopathic College in 1891. For several years past it has been settled in my mind theoretically that if it were practically applied it would prove such an adjunct to those cases of adhesions of the 'membrani tympania' and 'anchylosios' (quotations as printed in report; see Baltimore *Sun*, June 15, 1892) of the ossicles, conditions which it has almost been impossible to obtain from the past."

In the paper he gives his date as 1891 (the college opened in the fall of 1891, one year after his visit with Drane for treatment at my hands for deafness by "massage of the sound-conducting apparatus of the ear," or, as I have termed it since 1887, "otacoustic treatment").

In view of the steps taken by me to present the facts in this case, not only to the college of whose faculty Garey is a member, but the presentation by pamphlet to the yearly meeting of this school of medicine, known as the National Homeopathic Institute, they on the day of adjournment (June 17, 1892), through their "Senate of Seniors," which seems to preside over and decide upon ethical questions, made this report:

"We give notice to all concerned that violations of our code of ethics must not be allowed to pass unnoticed if medical associations are to be worth anything. And we would request our medical journals to make known the provisions of the code, so that our physicians may not err ignorantly."

And thus they teach; how different their practice!

J. A. MALONEY, M.D.

THE EVIL OF THE NOSTRUM.

To the Editor of THE MEDICAL NEWS,

SIR: The letter of Dr. Slifer in the August 13th issue of THE MEDICAL NEWS, on the pernicious effects of testimonials advertising secret and proprietary medicines, brings to mind another form of advertising in which the testimonial does not accompany the package containing the drug, but is sent broadcast in the form of a circular or letter, which usually consists of a fulsome indorsement of the preparation, and winds up with the signature of the indorser, to which are appended his titles, usually with the further fact that he is Professor of Cystoscopy and Prostatitis in the Podunk Medical College. It is evident that the *quid pro quo* in these cases is the advertising that the specialist obtains in having his name brought before the profession. The evil of it all is that preparations of little or no merit are thus foisted upon an unsuspecting medical public. Undoubtedly indorsements have been and are now occasionally given that express honest opinions, but the vast majority of them but thinly veneer the despicable methods of the sneak advertiser.

The profession of this city has recently received a circular letter advertising a proprietary medicine, which, if the assertions of the indorser are true, is deserving of a unique position in our materia medica. We give the circular in full, omitting, of course, the name of the writer and the drug:

"MAY 17, 1892.

"I reiterate my assertion made nearly a year ago, and am daily prescribing ——— with happiest effects.

"In my practice it accompanies the maid from her virgin couch to her lying-in chamber, assuaging the perplexities of maidenhood and easing the trials of maternity with most gratifying results.

"I earnestly hope that the proprietors of this valuable remedial agent will keep it up to its present standard of purity and excellence. —— ——— M.D."

The foregoing letter is apparently free from the methods of the surreptitious advertiser; at least nothing is apparently gained by the writer more than the slight tickling of personal vanity found in the wide circulation of an autograph letter.

A drug that can accompany a maid from a virgin couch to a lying-in chamber is certainly not devoid of power, and it should evidently be prescribed to young unmarried females with great caution. An ecbolic action

is hinted at when we are told of its "assuaging the perplexities of maidenhood and easing the trials of maternity," but we are left painfully in doubt by the concluding words of this sentence: "with most gratifying results." Whether "results" here refers to the maidenhood and maternity that have been assuaged and eased, or whether it relates to successes on other lines, is uncertain. Possibly diseases of men may be included within the curative range of this marvelous drug.

The letter concludes with a hope—born possibly of misplaced confidence—that the proprietors will keep the drug up to its present standard of excellence and purity. After the manner of some they shall not go on assuaging and easing until they have established a reputation, and then suddenly debase their products, thereby filling their coffers with much gold.

We too may be forgiven the pious hope that they will continue to assuage and ease, but we are doubtful of the propriety of accompanying a maid from a virgin couch to a lying-in chamber. We are of the opinion that she ought to follow much of this journey alone, or with only such assistants as the conditions of the case require. To intrude under such circumstances would suggest immodesty, even in the vender of a proprietary medicine. At the risk of being considered old-fashioned and puritanical, we certainly think that "accompanying," in the sense used in this indorsement, ought not to be permitted. Respectfully, MEDICUS.

CHICAGO, ILL.

RÖTHELN.

To the Editor of THE MEDICAL NEWS,

SIR: It was with interest that I took up the NEWS of July 30th and read your editorial on "The Differential Diagnosis of Rötheln, Measles, and Scarlatina." It was timely, inasmuch as epidemics of German measles are becoming common; and hence it is essential that the physician be prepared to recognize the disease when called to a case, particularly as it is acknowledged by recent writers of authority to be a specific, infectious, and highly contagious disease. To one who has not seen the disease in its various phases, a case of German measles may be difficult of recognition. In view of these facts, and with a desire to impart what information I have on the subject, and to emphasize what has already been said, I am led to report an epidemic that made its appearance in our midst during the latter part of last spring. Quite a number of cases came under my observation. Some were seen during the active stage of the disease, and others after this had passed. Upon inquiry, it was learned that the character of the malady was thought to be so mild by the parents that the services of a physician were considered unnecessary; consequently when, as health-officer, my attention was called to the cases, they were found to be without medical supervision.

The disease was confined to the children of four families in the same immediate neighborhood, with the exception of two cases. The parents of two or three of the afflicted families said that their children had been neighboring with a little girl in the vicinity who had a *breaking out*, and that they had *caught* the disease. To quote the remark of one little girl, she said to another: "I'm going to kiss you and give you the disease." To the children the so-called disease was a rash, making its appearance suddenly in the midst of apparent health, and, except in two or three cases, was followed by no untoward symptoms, the little patients keeping up all day, eating and sleeping without any apparent discomfort.

The eruption was upon the face, chest, and trunk chiefly, the extremities sharing lightly in it. So far as our observation extended, the face was the most common seat. The exanthem was most diverse in character. It varied between spots of a light-purplish hue and large blotches, some irregular in shape, others round; and, when abundant, with a tendency to coalesce, a flushed condition appeared. This was more manifest and characteristic upon the face than upon any other part of the affected surfaces. The next favorite seat was the chest. In some of the cases the fading of the rash was followed by a free branny or furfuraceous exfoliation; in others there was no desquamation.

In addition to the eruption the more indisposed had a slight rise of temperature; moderate angina; coryza, more or less pronounced; and decided induration and swelling of the lymphatic glands of the neck, and chiefly those of the anterior chains. The tongue presented a whitish coat.

In no instance was there an unpleasant sequel. There was one relapse; the case assumed its original phase, though the symptoms were somewhat intensified; speedy recovery ensued.

In this epidemic there were no fatal cases. The spread of the disease was prevented by strict quarantine.

L. P. WARRINGTON, M.D.,

CHARITON, IA.

INTOLERANCE TO POTASSIUM IODIDE.

To the Editor of THE MEDICAL NEWS,

SIR: THE NEWS of July 16th contains the report of a case of "Intolerance to Potassium Iodide," by Dr. J. T. Bringier, of Burnside, La.

It has seemed that such cases are of rare occurrence. I will relate my personal experience with the drug, which is more striking than in the case reported. During my school days I suffered with asthenopia, following an attack of measles. Various remedies having been tried without relief, it was decided to try potassium iodide, a then comparatively new therapeutic agent that was being vaunted as a panacea for all the ills to which flesh is heir. The prescribed dose contained about five grains of the salt. After the second dose, coryza set in and became more intense as I persisted in the continuance of the drug, so that a handkerchief would be saturated in a short time. There was pain across the bridge of the nose, as if it were placed in a vise and gradually compressed. Profuse lachrymation occurred, with a severe itching pain in the orbits, pain and ringing in the ears, and a feeling of pressure in the temporal regions. There was also profuse salivation, with congestion of the fauces, pharynx, and larynx. The involvement of the larynx was so profound as to embarrass respiration. It seemed that there was not a bone or joint in my body that did not share in the pain.

The acme was reached on the second night after commencing the ingestion of the drug (which was persisted

in), when it seemed that I suffered the torments of the damned. Sleep was out of the question. By morning the symptoms rapidly ameliorated, and, faithful to my charge, I consumed the four-ounce mixture, but there was no visible improvement of the asthenopia. On another occasion, following the ingestion of two or three three-grain doses of the drug at night, I was aroused from sleep and was obliged to arise to avert threatened suffocation. To the present day I manifest the same or even greater intolerance to the drug.

In my practice I have met with but one marked case of intolerance to potassium iodide.

F. P. BRUNTHAVER, M.D.

DOWLING, OHIO.

OPHTHALMIA NEONATORUM.

To the Editor of THE MEDICAL NEWS,

SIR: The article entitled "A Method of Infection, Treatment, and Prophylaxis of Ophthalmia Neonatorum," in THE NEWS of June 11, 1892, recalls an experience that I had while house-surgeon at Kings County Hospital in 1858.

Purulent ophthalmia broke out in the nursery building, a few hundred yards from the hospital. There were about fifty children inmates, most of whom contracted the disease, notwithstanding the employment of such precautions as were then known and available. The danger of infection from nasal discharges was a number of times demonstrated by accident. It was our practice to have the child held in the lap of the nurse, who also held its hands, while the physician grasped its head between his knees, controlled the eyelids with his left hand, and made the application with his right. Before releasing the child, or during the act, he (or she) would sneeze and blow the virus directly from its nostrils into the eyes of the nurse. In treating one refractory patient the nurse and myself each had an eye inoculated by a sneeze, each feeling the spray touch one eye at the same time. Both of us had the other eye diseased a few days later. The nurse became totally blind in the inoculated eye. I was confined in a dark room for several weeks, and did not recover the full use of my eyes for six or eight months, and have required occasional treatment for granular lids up to the present time.

The local treatment consisted mostly of solutions of silver nitrate, applied with a camel's hair brush, the strength varying from five to thirty grains to an ounce of distilled water. The standard strength, I believe, was ten grains to an ounce. One personal recollection I have was tasting the silver nitrate on the pharyngeal surface of my soft palate soon after its application to my eyelids. A number of times I had pencils of pure silver nitrate applied to my granular lids.

Yours, respectfully,

N. W. LEIGHTON, M. D.

BROOKLYN, N. Y.

NEWS ITEMS.

The Vermont State Medical Society will hold its seventy-ninth annual meeting at Montpelier, October 13 and 14, 1892. The following list of papers has already been secured:

The President's Annual Address, by Dr. C. S. Caverly, Rutland.

"Placenta Previa," by Dr. D. G. Kemp, Montpelier; discussion opened by Dr. C. C. Perry, West Rutland.

"An Analysis of Dosimetry, by Dr. C. W. Strobell, Rutland; discussion opened by Dr. W. H. Vincent, Orwell.

"Cholera Infantum," by Dr. A. E. Moody, Isle La Motte; discussion opened by Dr. George Davenport and Dr. E. Randolph.

"Uric Acid and Urea, Analysis and Significance of," by Dr. George B. Nichols, Barre; discussion opened by Dr. C. W. Peck, Brandon.

"The Influenza as Observed by Me in the Epidemic of 1891–92," by Dr. S. T. Brooks, St. Johnsbury; discussion opened by Dr. M. R. Crain, Rutland.

"Treatment of Minor Injuries to Workmen," by Dr. C. B. Ross, W. Rutland; discussion opened by Dr. C. E. Chandler, Montpelier.

"Some of the Medical Delusions of the Past and Present," by Dr. Edw. R. Campbell, Bellows Falls; discussion opened by Dr. H. A. Crandall, Burlington.

"Injuries to the Intestinal Canal, and their Various Modes of Treatment," by Dr. E. M. Pond, Rutland; discussion opened by Dr. J. N. Jenne, St. Albans.

"McBurney's Operation for Radical Cure of Hernia, with presentation of a case," by Dr. William F. Hazelton, Springfield; discussion opened by Dr. H. Janes, Waterbury.

"Neurasthenia," by Dr. A. J. Willard, Burlington; discussion opened by Dr. H. R. Wilder, Swanton.

"Diphtheria—Cause, Prevention, and Treatment," by Dr. F. R. Stoddard, Shelburne; discussion opened by Dr. C. F. Branch, Newport.

"The Insane Diathesis," by Dr. J. M. Clarke, Burlington; discussion opened by Dr. D. D. Grout, Waterbury.

"The Use of the Curette in Uterine Surgery," by Dr. Albert Vander Veer, Albany, N. Y.; discussion opened by Dr. L. M. Bingham, Burlington.

Paper (title to be announced) by Dr. B. J. Andrews, Burlington.

"Obituary of S. S. Clark, M.D.," by Dr. George Dunsmore, St. Albans.

"Obituary of Joseph Draper, M.D.," by Dr. H. D. Holton, Brattleboro.

The Executive Committee has decided to offer a cash prize of twenty-five dollars for the best original contribution on either of the following subjects: "Summer Diarrhea in Children" or "Treatment of Lobar Pneumonia," by a member of the Society. Papers shall not exceed 1500 words in length, and should be sent to the secretary, Dr. D. C. Hawley, Burlington, Vt., on or before September 15th.

Dr. Irving A. Watson, of Concord, N. H., will probably be present and read a paper on some sanitary subject.

BOOKS AND PAMPHLETS RECEIVED.

ORIGINAL ARTICLES.

THE NATIONAL GOVERNMENT SHOULD HAVE SUPREME CONTROL OF QUARANTINE AT ALL FRONTIERS.

BY E. O. SHAKESPEARE, M.D.,
OF PHILADELPHIA, PA.

IN discussing the importance of "What the State Can Do to Prevent Cholera," the recent Surgeon-General of India, J. N. Cunningham, M.D., very justly states that "the questions involved are questions of vast interest, not only to the people of India, but to the people of all countries. They involve the health and happiness of millions of homes in all parts of the world."

We have only to recall the immense losses that have been entailed upon most of the civilized and uncivilized nations of the world through the invasions of this disease to appreciate the great practical value which the solution of this question may have.[1] In India, where cholera rages constantly from year to year, the Sanitary Reports of the Indian Government for the eleven years preceding and inclusive of 1884 show that, during that period, the deaths from cholera in that country amounted to not less than three and a quarter millions, in round numbers.

In referring to the ravages of the epidemics of cholera in Europe, it is not necessary to summarize the detailed losses that have occurred since the first visitation by cholera in 1831, but attention may be called in this connection to the extent of the damage done by the epidemic previous to the present one. In 1883, Egypt is said to have lost 60,000 lives from cholera, and it is estimated that in 1884 and 1885 Italy and France together lost in the neighborhood of 60,000 inhabitants from the disease; to these numbers should be added the loss that Italy suffered during the years 1886 and 1887 from the same cause. The loss of life in Austria-Hungary has also been considerable. Spain, however, was the greatest sufferer from the ravages of cholera during that epidemic. Among a population of 16,000,000 there were, according to the official reports (which, no doubt, are short of the reality), 119,620 deaths from cholera. The records of the present epidemic, so far as we learn, show that the mortality in Russia, in Persia, and in India has been quite as severe as in the worst epidemics that these countries have previously suffered. For example, we are informed that the loss to Russia alone from this cause in the present year has already amounted to 150,000 lives, and yet there is very little indication that the epidemic has passed its acme. Before the end of this season in that country, in all human probability, the deaths from cholera alone will mount to upward of 200,000. Judging from the history of previous epidemics in Russia, in all probability the next year will witness a sacrifice of even more lives than have been destroyed during the present season there.

When one undertakes to estimate the loss to a country of the intrinsic value only of the lives destroyed, the amount, though great, must seem insignificant when compared with the loss of incalculable millions of treasure due to the paralysis of industry and commerce. Political economists in Europe have variously estimated the value to the State of a human life. It may be said that the average estimate places this at one thousand dollars per capita. Calculating upon this factor, we see that a destruction of value in Europe, represented in human lives sacrificed during the epidemic previous to the present one, has amounted to two hundred and fifty millions of dollars. Estimating the value to the State of human life in India, which, let us say, is one-tenth of that amount—that is, one hundred dollars per capita—we find that India has suffered a loss from this source alone, during the eleven years mentioned, of three hundred and twenty-eight millions, five hundred and sixty thousand dollars. No doubt political economists in America would estimate the value to the State of the average human life as greater than the sum named per head, and if we regard the statistics of death by cholera in former epidemics in the United States, we can readily perceive the enormous national loss that has been due to this cause. So that when Surgeon-General Cunningham, in discussing the subject of what the State can do to prevent cholera, purely from the practical standpoint, and speaking of the theories at present entertained or that have been entertained at various times by scientific bodies concerning the nature of the disease, says, "Whether these theories are scientifically correct or not is a matter of very minor importance,"

[1] Much of the facts and language in this connection have appeared elsewhere; in the main, in my "Report on Cholera in Europe and India," published by the Government Printing Office, 1890.

he can scarcely expect that many familiar with the history of the ravages of cholera in parts of the world outside of Hindostan can agree with him.

In view of the enormous interest the State (that is, the Nation) has in the prevention of the injuries that follow the uninterrupted spread of a wide and devastating epidemic of any kind, and particularly of cholera, I propose to discuss from this standpoint the question of national supremacy in the control of quarantine at all frontiers.

In the first place, regarding the estimation of the loss by the State in the destruction of human life alone occasioned by cholera epidemics, it can be readily understood that the loss to the public occasioned by a single widespread epidemic of cholera, or even of yellow fever or smallpox, is far greater than would be the cost of the proper maintenance for many years of a perfect quarantine establishment at all our ports. In the case of Asiatic cholera especially, but also in that of scarlet fever or smallpox in a lesser degree only, the relation of the enormous emigration from Europe into this country, as bearing upon the introduction of epidemic diseases here and their rapid dissemination throughout the land, should be closely considered. It cannot be denied that the entrance of the thousands of emigrants who annually reach our country after starting from or passing through localities infected with contagious diseases, frequently in their persons and in their pestiferous clothing carry with them often as far as their ultimate destination, and let loose there the active germs of these diseases; and the herding of these emigrants into the miserably ventilated and frightfully unsanitary quarters usually provided for steerage passengers on the trans-Atlantic steamships, the modern rapidity of ocean and land travel, and the great facility with which these swarms of people are so soon distributed all over our country, combine to multiply the danger to the public health, with which, in the laxity of our laws and the unsatisfactory administration of them, these incessant influxes constantly menace the country.

In their enormous numbers, their poverty and their squalor, and in their mode of transportation of all sorts of infections and contagions, these emigrants can be likened only to the Oriental pilgrims, in whose track pestilence has so frequently followed. It is, indeed, with the extremest rarity that smallpox or cholera has, in modern times, been introduced into North America by any travellers other than the immigrant class. To take the proper means to guard the ports of entrance against the infected persons and baggage of cholera emigrants would probably keep cholera from our midst; to do the same with smallpox emigrants, with the addition of compulsory vaccination and disinfection of personal effects, as an invariable condition precedent to the privilege of landing, would go far toward banishing that scourge from the land; and the importation of scarlet fever, diphtheria, and like diseases might likewise be prevented by similar adequate measures. The past history of cholera and a study of the mode of its spread during the present epidemic (in which its movement from east to west has been unprecedentedly rapid) shows that the main conveyors of the infection have been, this year, as in all previous times, the persons and personal effects of emigrants, pilgrims, or large masses of soldiers.

In 1887, when cholera reached the quarantine station at New York, it was brought there by emigrants direct from the port of Naples, where cholera was then raging. The introduction into South America, in 1886, of the seeds of cholera, and the widespread epidemic in Argentina, in Chile, and in neighboring countries, was due to the conveyance of the infection by an emigrant ship that sailed from Genoa at a time when cholera was present in that locality. Although examples of the conveyance of cholera in this manner might be multiplied almost indefinitely, it is unnecessary to more fully emphasize the well-known and indisputable fact that it is by the unrestricted movements of such people during the prevalence of an epidemic of Asiatic cholera that the disease has been conveyed from one country to another.

The establishment of quarantine has heretofore been the main means relied upon to prevent the introduction into any country threatened by the invasion of the seeds of this disease—and with varying results, according to the favorable situation of the given country with regard to the course of these infecting streams, and according to the hygienic condition of the threatened populations. Because of the inadequate quarantine establishments, oftentimes combined with exceedingly faulty administration, in the past, these methods of preventing an introduction have often necessarily failed, and the failure has (irrationally, to my mind) been ascribed, almost universally, to an impossibility of warding off cholera in this manner. In fact, the history of past epidemics is prolific in examples of complete protection of localities and of whole countries, when absolute non-intercourse has been adopted. In modern times, however, the serious damage done to trade by the adoption of such a sweeping policy has brought about an almost entire repudiation of absolute non-intercourse as a means of prevention. To my mind, in the case of the United States, so far distant from the source of cholera, and so remote from European shores, we need only to fear, during the prevalence of a widespread epidemic of cholera in the northern portion of Europe, the introduction

of the disease here through the numerous hordes of emigrants constantly arriving from Europe.

It is a fact beyond dispute, that cholera preys upon and breeds among those living in squalor and filth, and closely follows their movement. It is exceptional, even in Bengal, the home of cholera, that the Englishmen there are attacked by the disease. It is true, also, in filthy and frightfully unsanitary localities in Southern and Eastern Europe, that the intelligent and well-to-do classes suffer to no great extent during the period of a cholera epidemic. There is but little danger of the class of people who constitute the cabin passengers of the trans-Atlantic steamers bringing with them, either on their persons or in their clothing, the infection of cholera. It is for this reason that I hold most confidently that the chief and, I may say, the *only* source of danger of cholera finding a foothold, when inspection is properly performed at quarantine, lies in its introduction by the emigrant classes.

The establishment of a policy of non-intercourse, so far as emigration is concerned, during the times when Europe is suffering from a cholera epidemic, would, in my opinion, constitute the best, and perhaps the only means of safeguarding the general public from the ravages of this disease. I have repeatedly had occasion, in several publications and in communications to the medical and lay press upon this subject from time to time, to point out the dangerous state of imperfection, to my personal knowledge known to exist, in several of the Atlantic quarantine stations. The ports of Boston, Philadelphia, and Baltimore would certainly, in their establishments and in their limited corps of administration, be unable to cope successfully, for any long period, with an invasion through the emigrant classes who are allowed to come incessantly during periods of prevalence of cholera in Europe to our shores. Even the quarantine station at New York—which is the best, most completely equipped and best administered of all our quarantine stations—with the frequent arrival of trans-Atlantic steamers carrying infected emigrants, would quickly reach the safety-point of defence and be overwhelmed, unless we adopt the policy of long detention of travellers, ships, and cargoes—a policy which would involve a tremendous loss to those engaged in maritime trade or in any manner associated in a business way, directly or indirectly, with maritime commerce. The capacity of the New York quarantine station will be reached for purposes of safe defence with the landing of, say, one thousand infected emigrants. It can be readily seen how soon, with an uninterrupted stream of emigrants from infected localities, the capacity of this, our best quarantine station, would be taxed to the utmost.

In my opinion, the action of the President in attempting to suspend immigration, even in the indirect manner of enforcing quarantine of twenty days, is a wise procedure, and perhaps the only one that could be adopted under the present circumstances which would reasonably insure this country against an invasion of cholera. The placing of an embargo on immigration *only* would undoubtedly be the most direct means of accomplishing this desirable result, and would not be coupled with any harassing impediments to the course of trade, involved in the long detention of ships and cargoes, or harassing restrictions upon the movements of travellers who are but little likely to introduce the infection. It is needless to point out that with the ship's inhabitants limited to the crew and the cabin passengers, certainly the quarantine station of New York, in its present preparation, could be safely relied upon to guard the country against the introduction of cholera through that port. The present arrangements that have been adopted and placed in operation at the quarantine stations of Boston, Philadelphia, and Baltimore—imperfect as these are in establishment—would also be in no danger of being overwhelmed by the exigencies of the occasion. I regret to learn by the public press, however, that, while the authorities at the three latter quarantine stations have willingly acquiesced in the determination of the President, as expressed by the proclamation of a twenty-days' quarantine against all vessels carrying European emigrants, the quarantine physician in control of the port of New York has allowed himself to be prompted by a spirit of defiance, in claiming his right, under the laws of the State of New York, to entire independence of any national control, thereby assuming to nullify the efforts of the General Government to protect the general welfare. It is unfortunate for the country that the quarantine officer at the port of our metropolis, through which the vast majority of European emigrants pass, to spread widely through the whole of our country, should so lightly regard the duties and relations of a frontier quarantine officer to the safeguard of the United States and the welfare of the sixty-five millions of her inhabitants.

This example in itself affords sufficient reason for the establishment, by national legislation, under Congressional laws, of the supremacy of the nation in control of quarantine at all our frontiers for the safeguarding of the *national welfare*.

The ridiculously antiquated, obsolete, and inadequate permanent establishments at most of our maritime quarantine stations, and the apparent impossibility, except perhaps when confronted with emergencies such as the present, of obtaining appropriations from local authorities of sufficient sums of money for the erection of extensive and com-

plete quarantine establishments in accordance with modern science and accurate knowledge of the nature, mode of spread and means of prevention of cholera, are further and, to my mind, incontrovertible reasons why the general public cannot rely upon independent local quarantines for the defence of the whole country against the introduction of the common epidemic diseases, much less of epidemics of cholera.

In this connection the question may be very pertinently asked: Why, then, should the direction, expense, and responsibility of a system of common defence against the inroads of foreign diseases, any more than against invasions of foreign foes, be assumed and borne by those municipalities or States that happen to have a maritime location? Why should the vast majority located inland be allowed to shift their responsibilities and obligations or be denied a voice in the direction of affairs which so closely concern them? The protection of the public health by maritime quarantine is a matter that interests not merely a narrow belt of sea-coast; it seriously concerns the whole of the vast territory between our shores.

In view of the foregoing considerations I would therefore uphold the following propositions:

A. *The present methods of independent quarantine provided and regulated by sea-board States or cities are essentially defective and insufficient for the exclusion from the United States of the diseases against which quarantine is directed.*

The truth embodied in this statement is abundantly established by the report of the committee of the College of Physicians of Philadelphia, 1888, in regard to the three ports it inspected, New York, Philadelphia, and Baltimore, during the time of prevalence of cholera at the quarantine station of New York in the autumn of 1887. (Since the publication of this report, the quarantine station of the port of New York has been improved in one or two particulars—for example, a crematory has been put into active operation for the destruction of infective corpses; the large interiors of the two observation buildings on Hoffman Island have been divided into compartments for the better isolation of small groups of immigrants from infected steamers. This truth is fully borne out in regard to the other quarantine stations between the St. Lawrence River and the Rio Grande by the elaborate official report Dr. John H. Rauch, Secretary of the Illinois State Board of Health, made to that body in 1886, and the latest information shows that but little, if any, permanent improvements have been introduced in them.

The defects of local quarantine stations arrange themselves into two principal groups: (1) Inadequacy of establishment. (2) Faults of administration.

1. With regard to THE ESTABLISHMENT—which term is here used to include the accommodations for the temporary housing and care of immigrants and travellers not sick, adequate hospital accommodations for the sick, appliances for disinfection, and the necessary medical, nurse, police, and other attendants for the care of both of these groups of individuals—only four of the many stations upon the Atlantic and Gulf coast may lay claim to anything like adequate provision. These are Grosse Isle quarantine station on the St. Lawrence River below Quebec, the Boston quarantine station on Galop's Island, that in New York Harbor, and those in the Mississippi River below New Orleans.

Of these four it may be said: first, that the former excellent establishment at Grosse Isle is now dilapidated and practically useless as a safeguard against the importation of the disease, in view of the fact stated in the report of Dr. Rauch, that during the quarantine season up to October 9, 1885, only 32 vessels out of a total of 420 arrivals had stopped at this station for examination; second, that at the quarantine stations at Boston, Philadelphia, Baltimore, and I believe also New Orleans, no permanent provision for the housing and care of travellers and immigrants not sick exists; third, that in the last-named particular, as well as in several other respects, the quarantine station at New York, hitherto regarded as fully adequate to the requirements of that great port of entry, still shows defects. According to the official description by Dr. Joseph Holt, president of the State Board of Health of Louisiana, it would appear that the quarantine station at the mouth of the Mississippi is, in respect of means of disinfection, fully up to the requirements of modern science. Of the intervening stations it is scarcely necessary to speak. Certainly, as regards the prevention of cholera, and to a less extent also of yellow fever, the greater number of them constitute quarantine stations simply in name.

2. When we come to consider FAULTS OF ADMINISTRATION, it is obvious that it is impossible to discover their nature or extent during times of quarantine inactivity—that is to say, during those fortunately more or less prolonged periods in which the absence of disease upon incoming ships narrows the duties of the quarantine officials down to the simple inspection necessary to establish that fact at such times; we have therefore at present no criterion by which to judge of the efficiency of the quarantine administration at the greater number of the stations. The fact already mentioned with reference to the quarantine station at Grosse Isle, that during the quarantine season of 1885, up to October 9th, only 32 vessels out of the total 420 were examined, indicates defects in administration at that station so glaring as to require no further comment.

Faults of administration equally serious, although of a different kind, were shown by the above cited report of the committee already mentioned to have recently (1887) existed at the quarantine station in the lower bay of New York harbor at a time when cholera actually existed in the hospital, and was from day to day finding new victims among more than five hundred Italian immigrants detained at the quarantine of observation on Hoffman Island. It is only necessary to emphasize this statement by calling attention to the following facts brought to light by the investigations of that committee:

First, the absence of resident medical officers both at the hospital on Swinburne Island and at the quarantine of detention on Hoffman Island (this has been in the present emergency temporarily remedied); second, the absence of anything like an adequate sanitary police force on the latter island; third, the lack of any proper daily systematic inspection, such as would enable the authorities promptly to discover and isolate new cases of cholera—I mean the lack of direct subordinates of the quarantine officer constantly on board *all* detained vessels for the detection of looseness of the bowels—an exceedingly important matter in the case of cholera.

B. *It is impossible adequately to protect the public health of the country against the importation of epidemic diseases by independent local maritime quarantine establishments.*

Rival political and commercial interests are inimical to the perfect protection of the general public of the whole United States by independent and local quarantines.

One of the most serious dangers to which the general public is exposed through local maritime quarantine organizations is the possibility of bodies of immigrants with infected baggage being transferred directly from the quarantine station to distant inland communities by rapid railroad journeys, without any prolonged sojourn or without any adequate inspection at, or precautions being taken by the authorities of the seaboard cities through which they pass. In point of fact, this danger was realized in regard to cholera in 1873, when epidemic outbreaks of that disease occurred in Ohio, Minnesota, and Dakota, which were "caused by cholera poison packed up in the household effects of emigrants from Holland, Sweden, and Russia, respectively. *These emigrants sailed from healthy ports in healthy vessels, and were subjected to the usual sanitary requirements of the period. They passed through New York and the intermediate territory without injury to the public health; but when their infected goods were unpacked in the interior of the continent they liberated the poison which gave rise to the local outbreaks.*" (Report of Dr. Rauch.)

It is but natural that municipal organizations should, in looking after their own interests, pay little regard to the welfare of distant communities.

In this connection may be noted the indisposition and failure on the part of local quarantine officers to notify the authorities interested, of the arrival of emigrants from infected localities. Notwithstanding the frequent paramount interest of inland communities in the efficiency of the establishment and administration of quarantine at the seaboard, the local authorities of the latter frequently evince an unreasonable jealousy of any sort of investigation or suggestion looking to the general welfare.

In the absence of any general regulation or supervision, local quarantine measures must in the nature of things be exercised with varying degrees of efficiency; the most complete establishment and perfect administration at a few ports might, therefore, fail to protect the country if defective or inadequate measures of quarantine were practised elsewhere.

C.—*National supremacy of maritime quarantine is necessary.*

1. It is only in this way that the necessary protection against the importation of epidemic diseases in all our ports can be continuously secured.

2. It is the only practical mode by which uniformity of establishment and administration, regard being had to the modifications made necessary by difference of latitude and other circumstances, can be assured. Such necessary uniformity can be obtained by no other arrangement, for the reason that the National Government is alone able to defray the expense of complete quarantine establishments at every port, according to the requirements of each and without regard to the revenue derived from the shipping of any.

3. The benefits of quarantine inure to the welfare of the whole country; therefore, it is just that money should be as freely expended when necessary at one port as at another, without respect to their relative commercial importance or to the amount of revenue collected in the shape of boarding and inspection fees, etc. It is manifestly unfair that the seaboard cities and States should, as at present, be obliged to bear the entire expense of quarantine establishments whose most important function should be the protection of the inhabitants of every region of the vast territory of the United States.

4. A national quarantine, properly administered and conducted by trained officials, accustomed to deal with contagious and infectious diseases, would tend to prevent panic, to allay undue anxiety, and to favor a reasonable sense of security.

5. Experience has shown that much needless alarm, as well as preventable danger, arises upon the appearance of an unfamiliar epidemic disease

at quarantine stations, as when cholera has shown itself at New Orleans or New York, or yellow fever at Philadelphia or Boston. A national quarantine would very greatly lessen the necessity for vexatious temporary interstate quarantines, which so seriously disturb inland trade.

6. A national quarantine system, directed in such a manner as to fully meet the requirements of existing sanitary knowledge, would not adversely disturb any commercial interest. It would, on the contrary, do away with many of the embarrassments incident to maladministration of existing local regulations, and the enforcement of measures which are unnecessary and are prompted by a state of panic due to ignorance of the best and most reliable methods of prevention.

7. A national quarantine would not necessarily supersede any existing arrangements regarded as expedient by local authorities. It should constitute an outer line of defence under exclusive control of the National Government, and it should be conducted wholly without extra cost to shipping, and would thus work no additional pecuniary hardship, even if the present fees were to be still exacted by the local authorities.

8. The ability of the National Government by an existing Act of Congress to come to the aid of local quarantine authorities in answer to the appeal of the Executive of any State in time of grave danger implies a function of very narrow scope and uncertain application. Appeals of this kind are likely to be deferred until the emergency is extreme, and the aid obtained from the Government is therefore likely to be rendered too late to accomplish its most important purpose, namely, the prevention of an invasion.

D. *A national organization would secure advantages not attainable by independent local quarantine establishments, however complete.*

Among many other advantages the following may be enumerated:

1. Suitably arranged and commodious buildings provided with necessary furniture and appliances at all ports.

2. An efficient corps of trained officials and assistants always on duty.

3. The practicability of the concentration of force, money, and attention at any threatened port without loss of time.

4. Officials under the control of the National Government and free from local political and commercial influence.

5. The objects of quarantine would be furthered by full and reliable consular reports and sanitary inspection of emigrants at ports of embarkation, functions properly belonging to officials of the General Government.

The organization of a supreme national maritime quarantine system in the United States should require:

1. That the whole matter should be placed under an appropriate department of the General Government.

2. A central bureau of control established at Washington.

3. A sufficient corps of medical officers and assistants, with nurses, sanitary police, laundrymen, engineers, and officers and crews for boarding tugs, organized at every station. *Among the requirements for the medical service should be a speaking knowledge of at least two modern European languages besides English.* In view of the constant and systematic attempts to falsify the ship's log for the purpose of concealing the existence of infectious disease during the voyage, the health officers should be able when necessary to go among the passengers and *themselves* closely question them, without the mediation of an interpreter. The establishment of a school and laboratories for sanitary instruction and research in connection with this service would be an advantage. In addition to the men on duty at the respective stations, there should be a sufficient number of medical and other officials fully trained in quarantine duties and familiar with contagious diseases, unattached and available for immediate auxiliary service at any threatened port.

4. The erection of necessary hospital and other buildings, wharves, disinfecting apparatus, washhouses, latrines, etc., in suitable localities, when possible upon islands at or near the entrances to harbors, and at some distance from the main channel.

5. These stations must be organized and fully equipped at every port of entry of the coast in such a way as to meet the requirements of each port in the measure of its commerce and immigration and the especial diseases to which it is most exposed.

6. The cost of the establishment and maintenance of the national maritime quarantine should be provided for by appropriation from the National Treasury, and not from fees exacted from vessels.

The danger from immigrants would not be entirely banished, however, though the quarantine of the coast of the United States were perfect, for the way through the British Provinces would still be open to these travellers. In the absence of efficient quarantine inspection in the St. Lawrence River and in Nova Scotia, the attempt thoroughly to protect ourselves from importations of epidemics would necessitate the doubtful and difficult expedient of a land quarantine along our northern frontier. The more efficient plan would be to have the same precautions taken at the ports in the British provinces as should be practised at those in the United States; but this course could only be assured through treaty

or international agreement, which our local authorities are not competent to make.

It appears that our Canadian neighbors have already evinced their desire for uniform quarantine laws for the two Governments. The Provincial Board of Health of Montreal, recognizing a community of interest in the question of maritime quarantine, deemed the presence of the Canadian Fish Commissioners in Washington opportune for the adoption of resolutions requesting the Commissioners to urge upon the American authorities "the necessity of establishing uniform quarantine regulations for both countries." In connection with an efficient system of national quarantine a harmony in the provisions of law in the United States and in Canada seems indispensable for the full protection of our extensive northern frontier, and our National Government should be strongly urged to respond actively to the expressed wishes of the Canadian authorities relating to such an important matter of common interest.

PROPHYLACTIC MEASURES AGAINST ASIATIC CHOLERA.

BY A. C. ABBOTT, M.D.,
FIRST ASSISTANT, LABORATORY OF HYGIENE, UNIVERSITY OF PENNSYLVANIA.

WITH the existence of Asiatic cholera in the western seaports of Europe, the question involving its possible importation into this country becomes a grave one, and it behooves us to exercise the greatest vigilance in endeavoring to prevent such a calamity.

There is no doubt that the suggestion, radical though it is, that has recently been made to the President of the United States by the Medical Board of the Johns Hopkins Hospital, at Baltimore, viz., that immigration be entirely interrupted until after the disappearance of cholera from the western cities of Europe, is by far the safest measure that could be employed. It is practically impossible, by the means ordinarily employed, to disinfect and render harmless every article from an infected ship; and, unless this is done, there can be no assurance that the disease will not be introduced, through articles contaminated with the disease-producing element, into localities to which such articles are carried.

Should it not be considered wise to check absolutely all immigration into the United States until after the disappearance of the disease from the infected ports of Europe, there remains to be considered the question of quarantine. Quarantine, if maintained for a sufficiently long period, offers a certain guarantee of safety against the spread of the disease through the bodies of individuals who come from the plague-stricken districts; for they are usually detained for a length of time sufficient to permit of the appearance of the disease had the causative elements gained entrance into their bodies; but, as is most commonly the case, the means employed for disinfecting the personal effects of these individuals that arrive along with them on the same ship are of but little value; and it is through the channel afforded by soiled and infected bedding, clothing, etc., that the greatest danger is to be anticipated.

Another point that is worthy of consideration in connection with the subject of quarantine and of absolute cessation of immigration is whether or not it would avail us much without the institution of similar measures by our neighbor, the Dominion of Canada, into whose eastern seaports immigrants are constantly arriving from the same places as those from which come the immigrants against whom we are taking such radical steps. With Canada separated geographically from the United States by only an imaginary line, it must be plain that it would be practically folly for either country to close its doors against the tide of immigration without similar steps on the part of the other; for, unless they act in unison, the tide will simply be deflected from the closed to the open way, and, related geographically as both are, the existence of cholera in either place would be a menacing danger, if not a practical assurance, of its appearance in the other.

As yet, thanks to the vigilance of the health officials along the Eastern seacoast, there has been no appearance of the disease among us, but in anticipation of such a visitation it might be wise to consider the measures that are known to be most effectual in checking its spread.

Of primary importance in the management of cases of cholera, is of course an accurate diagnosis of the condition; and fortunately this offers but little difficulty to the skilled clinician, particularly if it has been his privilege to have seen the disease before, and still more especially if it is in his power to bring bacteriologic methods to his aid.

When recognized, the management of these cases and the methods of prophylaxis against their spread depend so largely upon absolute isolation and attention to sanitary surroundings that too much stress cannot be laid upon these points.

By isolation is not meant simply the confinement of a patient in a room or apartment set aside for infectious maladies, but it comprises a great deal more: it must be absolute, or the sense of security that it affords becomes false, and is, therefore, worse than useless. The isolation of a patient with this disease or with any other form of highly infectious malady implies the provision of separate apartments; an attendant whose duties are confined to patients who are similarly affected; plates, dishes, bed-pans, bed-clothing, etc., that are used by no other patient;

and a rigorous disinfection of all excreta, vomited matters, and refuse food *before they are removed from the apartment occupied by the individual.* It involves the greatest care and intelligence on the part of the attendant, to close all channels through which he or she and the patient may become a source of contamination, for contamination and spread of these diseases occur almost as frequently through the attendant as through the patient. The reason for this can be appreciated only after an intimate acquaintance with the nature of the causative element and its peculiarities when outside the body of the diseased individual.

Studies that have been made upon Asiatic cholera in recent years have shown it to be of an infectious nature and due to the activities of a specific lower organism which is present in the intestinal canal of all infected persons. This organism belongs to the family of bacteria. It is a bacillus, comma-shaped or curved in its morphology, and presents peculiarities of growth and chemical reactions that render its identification by the bacteriologist a matter of certainty and of a fair degree of simplicity. As a result of studies upon the nature of this organism, when isolated under artificial conditions, it is found to possess a relatively low degree of resistance to both thermal and chemical agents—that is to say, its vitality and disease-producing properties are easily destroyed by heat, and it quickly becomes inert when subjected to those chemical substances that are known to possess germicidal qualities. It likewise loses its resistance when *absolutely* dried, but retains it for a longer or shorter time when the drying is not complete. Having gained access to water, its growth seems to depend upon the amount of organic matter present, the reaction of the fluid, and also upon the number and kinds of other organisms that may be present, for, owing to the antagonism that is seen to exist between different species of bacteria, it not uncommonly occurs that one species or group may develop entirely at the expense of the other, which quickly disappears.

Milk offers a most favorable nidus for its growth, as do likewise many solid materials used as food-stuffs, and particularly after they have been cooked. The bacillus is very sensitive to both acids and alkalies, and is quickly killed when subjected to the influence of either. As has been stated, it is located in the intestinal tract of the affected individual, and therefore appears in enormous numbers in the intestinal evacuations from these patients; and it is through these evacuations that the disease is usually disseminated.

Some of the more common channels through which diseases of this class are transmitted are drinking-water, milk, and solid food-stuffs that are eaten in an uncooked condition, such as salads, fruits, etc.

Bearing in mind the points that have been here hastily reviewed, it is easy to comprehend the value of measures that will now be suggested for prophylaxis against the disease.

During the existence of an epidemic of Asiatic cholera—

1. No food, of whatever character, should be eaten in an uncooked condition.

2. All water intended for drinking purposes should be heated to a temperature of 80° C. (176° F.) for half an hour, or boiled for ten minutes and allowed to cool before using. When iced, the ice should be placed around the vessel containing the water, and not in it, as ice may contain organisms that have not been rendered incapable of development by the low temperature to which they had been subjected.

3. Milk should be steamed in a vessel placed within an ordinary kitchen steamer (if a regular sterilizer is not at hand) for fifteen minutes, and allowed to cool before using. The same precaution as regards icing is to be taken as was recommended for water. A somewhat lower temperature may be employed if care be taken that it does not fall below 80° C. (176° F.), for half an hour. This method requires a little more care, but causes less alteration of the milk than that following the application of a higher temperature. If the milk is to be kept for any length of time after heating, it is better to heat it in clean bottles plugged with cotton-wool. These bottles are placed in the steamer and heated for the proper length of time. They are then removed, kept in a cool place, and their plugs not removed until the milk is to be used.

4. Salads of uncooked materials are to be dispensed with, and all vegetables, fruits, etc., particularly those coming from districts in which "night-soil" is employed as fertilizer, are to be thoroughly boiled or otherwise cooked before using.

5. If possible, a daily bath in warm water, with the use of soap, should be indulged in, and the teeth should be carefully brushed after each meal. In short, rigorous attention to personal hygiene is of greatest importance.

6. In the management of cases of Asiatic cholera, isolation should be as complete as possible. Wherever practicable, tents on open lots, lawns, or fields are perhaps the best shelter for the sick. These patients should be provided with special nurses, who are made thoroughly aware of the fact that they themselves afford as potent a channel for the dissemination of the disease as do the patients themselves. These nurses should come in contact with no one other than the patient and physician. They should be impressed with the necessity of rigorous attention to their personal hygiene, frequent baths and changes of clothing being all-important. The

nurse should under no circumstances partake of food in the apartment occupied by the patient, and never partake of any portion of the food remaining from the meals of the latter. Before meals her hands should be scrubbed with soap, brush, and hot water, and after drying be rinsed off in 1:1000 solution of corrosive sublimate and dried.

7. The evacuations and vomited matters of the patient should be disinfected *as soon as passed and before they are removed from the apartment.* This is best accomplished by thoroughly mixing them with ordinary milk of lime (fluid "whitewash") until the mass is of a *distinctly alkaline reaction.* They should remain in contact with the lime for from twenty to thirty minutes. After this they can with safety be emptied into the general receptacle for such matter.

8. Bed-pans, bed-clothes, etc., that have been soiled by the evacuations of the patient must be cleansed by boiling for from *twenty to thirty minutes* in water to which about 1 per cent. of common soda has been added.

9. Mattresses should be subjected to sterilization in a *steam sterilizer for one hour.* If this is impossible, they should be burned. It is difficult to render harmless such large objects without injury to them, and unless the facilities are perfect these objects should be completely burned.

10. All clothing, towels, and napkins from the patient should be placed in clean canvas bags and conveyed from the apartment. At a proper place, arranged for the purpose, they should, without being removed from the bags, be sterilized in a steam sterilizer at 100° C. (212° F.) for one hour. They can then be removed and washed with safety. If it is not possible to employ steam they can be packed in an ordinary wash-boiler and boiled for half an hour in water to which 1 per cent. of common soda has been added. Care should be taken that each article is thoroughly soaked by the water during the boiling.

11. All dishes, knives, forks, spoons, etc., used by the patient should, after each meal, be boiled in 1 per cent. soda-water for half an hour.

12. The remains of meals should be thrown into a vessel containing milk of lime. At the end of each day, the vessel should be emptied into the general receptacle for feces, etc., and refilled with the milk of lime for the next day's use.

13. If practicable, the patient should be bathed as often as circumstances will permit, and the nates, thighs, and anus thoroughly cleansed with soap and water.

Before closing, emphasis will again be laid upon the necessity of *isolation* in the sense laid down in the foregoing directions: Separate attendants, who do not come in contact with other attendants whose duties take them to patients sick of other diseases; special clothes, bed-clothes, dishes, knives, forks, spoons, napkins, towels, etc., for each patient, and a careful disinfection of the same as soon as they have been used, and are ready to be removed; disinfection of excreta with milk of lime *at the bedside, or before removal from the apartment.*

After the death or removal from the apartment of the patient, the walls should be wiped down with moist cloths, sponges, or fresh bread-crumbs. These are to be burned as soon as used. Floors should be scrubbed with ordinary soap after having been *saturated* with a solution of 1 : 1000 corrosive sublimate. Furniture should be thoroughly wiped with cloths soaked in 1 : 1000 corrosive sublimate solution. All cotton or woollen materials in the room should be either steamed or boiled, according to the rules already given for bedding, clothing, etc. The room should then be thrown open to air and sunlight for several days.

In the event of death, the body should, without being washed, be immediately wrapped in sheets, placed in a coffin, and buried or cremated as quickly as possible. If buried, it should be placed beneath the surface at a depth of not less than six feet, and not in the near vicinity of a spring or watercourse.

There is absolutely no objection to burying the bodies, providing the interment does not take place in a locality where a spring or watercourse could be directly contaminated; indeed, on the contrary, experiment has demonstrated that this method of disposing of infected materials is second to cremation only in its requiring a somewhat longer time for the accomplishment of the same end.

The foregoing directions comprise those sanitary measures that have been found by experience to afford the greatest protection against the contraction and spread of infectious diseases generally, and particularly of that class of diseases of which Asiatic cholera is a representative.

NOTE.—In times of epidemic, the most common prophylactic measure is, perhaps, fumigation by means of sulphurous acid. This is usually accomplished by burning sulphur in the infected room. In order to carry out this measure with any degree of certainty that it is doing what one desires, a great deal of care and detail is necessary, and for that reason it is not a measure to be recommended for general use. By the ordinary means that are employed in fumigation, practically nothing of good is accomplished. It is, however, possible to disinfect apartments by this means if they are closed as tightly as possible, by pasting paper over the cracks about the doors and windows, and burning not less than from a pound to a pound and a half of sulphur for every 1000 cubic feet of space to be disinfected. Even then the best results are obtained only with

the simultaneous generation of steam in the apartment, or by previously having moistened every crack and crevice in the wall, ceiling, and floor with water. The reason for this is that sulphurous-acid gas in a dry state or upon dry objects has but little germicidal value; this property is only developed in the presence of moisture.

NOTES ON THE DIAGNOSIS AND TREATMENT OF CHOLERA.

BY WILLIAM OSLER, M.D.,
PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

THE welfare of an entire community may depend on the early recognition of the nature of the disease. With an outbreak at our doors, so to speak, the physician will scrutinize sharply all dubious cases, and in a natural anxiety to protect the patient and his family from trouble and inconvenience, will remember also the larger obligation to do all in his power to prevent the spread of one of the most formidable of human scourges.

The diagnosis of Asiatic cholera, easy and clear during the prevalence of an epidemic, may be at its outset (and under certain circumstances) exceedingly difficult. The clinical features of the disease and the bacteriologic examination of the stools furnish the data upon which to base an opinion.

A. *The clinical picture.* Here we are at once confronted with the lack of symptoms distinctive of, and peculiar to, the disease. A case of cholera nostras (morbus) may present every feature of the imported malady; and though it rarely kills with the same rapidity, yet I have known death to follow in an adult within fourteen hours. The preliminary diarrhea, the vomiting, the copious serous discharges, the collapse, and cyanosis offer no differential criteria.

It is only, however, during "cholera times" that this difficulty becomes serious; and then during the summer months, if the number of cases increases rapidly, it may tax all the resources of our art to reach a positive conclusion. The recent experience in Paris is, in this respect, most instructive. Throughout the months of May, June, and July, an epidemic of choleraic diarrhea broke out in certain of the suburbs that received polluted Seine water, and more than four hundred deaths occurred. The disease, which was called cholera nostras, choleriform diarrhea, and cholerine, in many instances killed within a few hours and had all the clinical characters of the Asiatic form; but the persistence in certain localities, without rapid extension, and the freedom of the city proper, encouraged the hope that it was due to intrinsic and not to extrinsic causes.

Dupuy's interesting report from the Hôpital St. Denis describes a disease of abrupt onset, a rapid course, and of great fatality, thirty-one deaths occurring in sixty-five cases. There seems to have been a disposition on the part of the authorities to conceal the serious nature of the epidemic—partly, no doubt, in consequence of the absence at first of positive bacteriologic information, and partly owing to the difficulty in obtaining uniformity in the opinion of the physicians, some declaring it to be true cholera, others that it was only a somewhat widespread endemic of cholera nostras.

Since, then, it must be acknowledged that in individual cases and even in local outbreaks, it may not only be difficult, but even impossible to distinguish clinically the two affections, the physician should, from the outset (particularly at the present juncture, when an outbreak may occur), take precautions as if dealing with true cholera, especially in carrying out disinfection of the stools.

It is of the greatest importance to see cases early, before the symptoms of collapse appear, and people should be instructed to seek advice on the first indication of gastro-intestinal disorder. Dyspeptic conditions and diarrhea, often premonitory symptoms, give timely warning in many instances, but by no means in all, for an individual may go to bed feeling quite comfortable and awaken during the night with cramps, vomiting, and diarrhea.

It is scarcely necessary to refer to the attacks simulating cholera produced by arsenic, corrosive sublimate, and certain fungi.

B. *Bacteriologic examination.* This is of the first importance, and should be carried out by experts who have critical familiarity with the complex flora of the intestines. Though there are difficulties, the differentiation of the comma-bacillus of Asiatic cholera can be made, and has been made in the recent outbreaks in Paris by Netter, Chantemesse, and Roux. In all doubtful cases, measures of isolation and disinfection should first be used, and then a thorough examination carried out to determine the presence or absence of the comma-bacillus.

It seems almost an abuse of terms to speak of the *treatment* of a disease of which the mortality is at least 50 per cent.; but although measures are futile in the more malignant cases, there can be no question that prompt action may arrest progress in the less severe forms, while we have at our command the means of alleviating many of the most distressing symptoms.

The experiments of Haffkine encourage the hope that protective inoculation may yet reach a satisfactory position and be more worthy of confidence than the vaccination of Ferran, but we have no ready method at present available. The ideal treatment would be found in a remedy that, given early,

would either control the multiplication of the bacilli in the bowels or neutralize the action of their poisonous products. Several drugs have been recommended for this purpose—salol, particularly on experimental grounds, by Loewenthal; and reports from various sources speak of good results. The drug may be given freely, in doses of from gr. xv to xxx every hour at first, for four or five hours, and subsequently every three hours. It probably acts by retarding the growth of the organism. There is no known remedy that is directly antidotal to the cholera poison. Brunton has advised atropine, to counteract the supposed contraction of the pulmonary arterioles, regarded by Sir George Johnson as the cause of the cyanosis.

The symptomatic treatment should be directed to—

a. Relieving the collapse by hot stimulants, as tea, coffee, brandy, and the external application of heat in various ways. The hot bath should be tried.

b. Checking the vomiting. Cracked ice and champagne, creasote, hydrocyanic acid, menthol, and other means may be tried.

c. Checking the diarrhea. There can be no question that the collapse is directly due to the diarrhea, and yet it is probably an effort of Nature to get rid of the poison. Indeed, an evacuant treatment has been urged by Johnson, who advises the use of castor-oil; but the general opinion runs strongly in favor of the use of remedies to check the profuse discharges. Various combinations of opium and ether are employed, with or without astringents. Morphine, hypodermatically, is of the greatest value for this purpose, and is to be preferred to opium by the mouth if the vomiting is obstinate. It has the advantage also of quickly relieving the pains and allaying the terrible restlessness. Lactic acid has been strongly recommended by French physicians.

Two special measures may be given a thorough trial, viz.: *hypodermatoclysis* and *enteroclysis*. The former Cantani urges upon the following grounds:

"1. The death of cholera patients supervenes either by asphyxia in the algid period or in consequence of a tumultuous reaction in the typhoid stage, because the organism, through diarrhea and vomiting, has lost a very large quantity of its aqueous constituents, and has retained or cannot longer eliminate the excrementitious materials—the products of combustion and decay—on account of suppression of the functions of the kidneys.

"2. Recovery occurs when absorption is resumed, in the intestinal canal, of the fluids which furnish to the blood and to the tissues the water which is indispensable to them."

The formula which he advises is as follows:

℞.—Sodium chloride . . .	80 grams.
Sodium carbonate . . .	6 "
Boiling water . . .	2 liters.

With a fountain-syringe and the canula of an aspirator, from one to two liters of the fluid is allowed to flow gently beneath the skin of the flanks. The tumor formed by the fluid is slowly rubbed away. He advises the warm bath in conjunction with the infusion. The operation may be repeated in two or three hours.

Enteroclysis is even more warmly recommended by Cantani, a mixture of laudanum and tannic acid being employed. The following is the procedure: "If a slight attack of a seemingly simple diarrhea does not yield at once to rest in bed and the administration of a dose or two of warm infusion of chamomile, to which chlorodyne or laudanum has been added in proper quantity, then recourse should be had, without loss of time, to the warm enteroclysis of tannic acid. This enteroclysis is essentially an injection into the colon, per rectum, of a considerable quantity of warm water holding in solution a certain percentage of tannin. The rectal syringe, by means of which the injection is made, is furnished with an elastic tube three meters in length, with a nozzle at the free extremity and a cock at the proximal end. With such an instrument not only the whole length of the colon can be filled with the desired fluid, but also not infrequently a quantity can be made to pass beyond the ileo-cecal valve into the small intestine.

"The tannic solution recommended by Cantani is constituted for an adult as follows:

"℞.—Boiled water or infusion of chamomile, warm	2 liters.
Tannin . . .	5 to 10 grams.
Laudanum . . .	30 to 50 drops.
Powdered gum arabic .	50 grams.

"The temperature of the mixture and the quantity to be injected should vary according to the age of the patient and other circumstances, in the judgment of the physician. The most convenient time for administration of an enteroclysis is immediately following an evacuation." (Shakespeare.)

BRIEF SUGGESTIONS AS TO THE PREVENTION, RECOGNITION, AND TREATMENT OF CHOLERA.

BY ROLAND G. CURTIN,
OF PHILADELPHIA.

IN view of the probable visitation of the Asiatic scourge, it may not be amiss, at this time, to call attention to some of the more practical features of the disease.

First, as to *prophylaxis*. The prevention is better than the cure. After the germ has obtained a foot-

hold, what is the proper course to pursue to guard against the disease?

The first important step is to keep the body and its surroundings perfectly clean. The body should be frequently bathed and the clothing changed. See that all cellars are free from contaminating substances, and all privies and gutters properly disinfected. Avoid crowding, as this favors the propagation of the disease. Eat moderately of good, nutritious food (don't starve yourself). Avoid fatigue, exposure, intemperance, and all excesses or anything that has a tendency to depress the vital energies. Take a full amount of sleep at regular intervals. Regularity and temperance in all things are of the utmost importance.

All drinking-water and milk should be boiled—this being especially important in Philadelphia, owing to the danger of the water being contaminated in its passage through the Schuylkill valley above the city. Avoidance of all saline laxatives i is a safe rule during an epidemic.

I will quote from an article of mine entitled "Sulphuric Acid as a Prophylactic in Cholera," published in the *Philadelphia Medical Times*, July 12, 1873:

During this last visitation (1866–67) I was resident-physician in the Insane Department of the Philadelphia Hospital. The disease had almost entirely disappeared from the city and from all parts of the Philadelphia Almshouse and Hospital, except from the women's wards in the insane department, where it still continued in a very virulent form. Strange to say, it was almost entirely confined to three of the seven wards on the female side of the hospital. It was so persistent that the Board of Health paid the hospital an official visit, but were unable to account for the presence of the disease in particular wards. It is true that the women's apartments were very much crowded, there being three hundred and fifty inmates, but the wards in which it was so prevalent had proportionately fewer inmates than others which almost entirely escaped. During the whole epidemic only two cases occured in the male wards, while among the females one in every nine was attacked. Sex would not account for this difference, for statistics at large show that male and female lunatics are equally liable to the disease.

After having concluded to use sulphuric acid, the next thing was to administer it to all the patients, many of whom were so suspicious that they refused at all times to take medicine, for fear of being poisoned. Knowing that it would be impossible to conceal it in their food or usual drinks, I concluded to administer it disguised as lemonade, and announced through the nurses to the patients that I intended to "treat" the whole institution to lemonade every day, which announcement was well received in general, and by some of them with enthusiasm. The drink was made in this way. About twenty drops of the dilute sulphuric acid were mixed with four ounces of water and sweetened with white sugar. Some oil of lemon and a few cut lemons greatly assisted in the disguise. What followed the administration of the sulphuric acid can best be shown by the notes taken at the time. The diary was begun on August 20, 1866, before which time seventeen cases had occurred in the insane department.

August 20.—Four new cases.
August 21.—Four new cases.
August 22.—Four new cases.
August 23.—Two new cases. Board of Health visited the hospital.
August 24.—Five new cases.
August 25.—One new case. Acid given for the first time, in the afternoon.
August 26.—Four new cases *during the early morning hours* within twelve hours after the first administration of the acid.
August 27.—No new cases.
August 28.—One new case—a woman who refused to take the acid.
August 29.—No new cases.
August 30.—No new cases.
August 31.—No new cases. The acid was discontinued.
September 1.—No new cases.
September 2.—Two new cases—two days after the suspension of the acid.
September 3 —No new cases. Acid resumed.

The acid was continued for some time, and no more cases occurred.

It will be seen by the above diary that up to the time of administering sulphuric acid the disease was pursuing a steady course in the female department. It is true, and should be here stated, that every means had been tried to banish the disease, such as ventilating and cleansing the wards, spreading disinfectants, scattering the patients by using a large sewing-room for a sleeping ward, attention to diet, etc., but without apparent effect. The acid was first given on the 25th of August and continued until the 31st. Four cases occurred *within twelve hours* of the time when the acid was first given. After this only one case occurred while the acid was being used, viz., on the 28th. This was a poor ignorant (?) lunatic, who, upon tasting it, spit it out, and surprised me very much by saying, with great vehemence, "Doc-ther, ye call this limonade; but ye can't desave me; it's nothing but ile of vitriol." On the 31st of August it will be seen that the "lemonade" was stopped, on account of the exhaustion of the supply of white sugar in the drug store, as without this sugar it would have been impossible to prepare the acid in such a manner as to insure the patients' taking it. On the 2d of September, *two days after the suspension of the use of the acid, two new cases occurred*, both of which proved fatal. The prophylactic was then resumed, and *no new cases* afterwards occurred in the insane department; but cases continued to arrive from the city until the 1st of November. The use of the acid was continued uninterruptedly for several weeks. My friend Dr. J. F. Wilson gave it to the patients in the surgical wards during the epidemic, and he informs me that *cholera visited every department of the almshouse and hospital except the surgical wards.*

The question naturally arises, was it the sulphuric acid that arrested the march of the disease? I think it was, for the following reasons:

1. *The prompt disappearance of the disease within twelve hours of the time when the acid was first administered*, the only case arising during its use being that of a patient who refused to receive it. The acid was stopped on the 31st of August, and two days after this two cases occurred. The acid was then immediately resumed, and not a single case occurred afterwards.

2. *The fatality attending the disease.* When an epidemic declines from natural causes, it generally becomes less fatal. Of the four patients attacked on the 26th of August, three died, of whom one was a young, robust epileptic, who lived but five hours after the first symptoms; another was a strong lunatic, who succumbed in nine hours. The two cases which occurred on the 2d of September, after the suspension of the use of the acid, both died, thus showing that the type was none the less fatal.

How did the sulphuric acid act? According to Dr. G.

B. Wood, it has the following effect upon the system, viz., *tonic*, *astringent*, *refrigerant*, and diuretic. It has been largely used in the treatment of the first and second stages of cholera. Dr. Macnamara, in his work on Asiatic Cholera, recommends the use of dilute sulphuric acid, in doses of fifteen minims, in the second stage. The celebrated "Austrian Specific" was composed of sulphuric and nitric acids. Nitric acid had been used in India in the treatment of cholera with considerable success. It was tried in England and found to be of no avail, when further investigation proved that the nitric acid of India contained a considerable amount of sulphuric acid. The latter was an accidental product of the manufacture of the nitric acid in India. Hence the use of the combination of these two acids in the treatment of cholera. Elixir Hallerii, or liquor acidi Hallerii, has been much used in India, and is ordered as part of the medical stores of the British army there. It consists of sulphuric acid and alcohol. Drs. Buxton, Sansom, and Fuller, of England, used sulphuric acid with success in the first stages of cholera, especially in the choleraic diarrhea. From the above statements it would appear that sulphuric acid itself has some effect upon the disease, and now we will proceed to discuss its influence as a prophylactic.

It had been noticed that workers in copper were remarkably exempt from cholera, and upon investigation it was found that the air surrounding them was considerably charged with sulphuric acid, which gave rise to the supposition that this was the active preventive agent. This led to the use of sulphuric acid in cholera districts and hospitals, but with what results I have not been able to learn.

It has already been stated that sulphuric acid may act beneficially independent of any specific action upon the cholera germ.

I have said that it is a tonic, astringent, refrigerant, and diuretic. The vital energies are often very much reduced, digestion is poor, and the intestines and the system at large are in a relaxed condition, the result of the high temperature of summer. Here we find the condition favorable to an attack of cholera. The tonic, astringent, and refrigerant effects of the sulphuric acid would all be eminently indicated by the conditions, and its administration might tide the patient over the period of danger. It may also act beneficially in another way. We all know the depressing effect of fear, which undoubtedly predisposes to cholera. A prophylactic given in such cases would allay the fear and thus ward off the disease.

It would seem that the article is of more importance since the comparatively recent discovery of the comma-bacillus, which cannot live in an acid medium. May this fact not account for the efficacy of sulphuric acid as a prophylactic? The germ is, perhaps, destroyed in the alimentary canal before the products of its activity are taken up by the system. The remedy is in any case well worth a trial; for, if it should only allay the fears of the timid, the otherwise resulting depression might be avoided.

Diagnosis and Treatment. It is most important to recognize the disease in its earlier stages; for at this period simple treatment is usually attended with success. Later on, in the cold stage, or in that of collapse, about 50 per cent. die, even under the most skilful management of the physician and nurse.

What are the first symptoms of cholera? The *first stage* is the forming stage or *stage of invasion*, sometimes called *cholerine*, or the *diarrheal stage*. The intestines are in an irritable condition. The discharges are at first yellow and fetid; later on becoming whitish or grayish, and being composed of serum and epithelium. Fibrinous flakes are sometimes present and the stools are blood-stained. This is the stage of invasion. It may come on abruptly, or gradually. Death may, in some rare cases, take place without vomiting or diarrhea. I had an opportunity of observing two such cases at the Philadelphia Hospital in 1866. At the autopsy the stomach and intestines were found filled with the so-called "rice-water" material, which usually constitutes the discharge in cholera.

Sometimes the first stage is abruptly ushered in with restlessness, wakefulness, noises in the ears, languor, depression, headache, muscular weakness, and a weak, small pulse.

In the cases of insidious onset the earliest symptom is a mild diarrhea. The stools are at first yellow, afterward watery, copious, and frequent, with abdominal pain, slight tympany, borborygmi and nausea. The extremities, especially the lower, become painfully cramped.

This stage may last several days, or only for a short time, and may escape observation altogether. Prompt measures at this stage may stay the disease; hence the importance of recognizing the earliest symptoms.

Thoughtless persons and children are usually the ones that allow this stage to pass by without attention. Such persons should be carefully watched by those having charge of them.

During an epidemic, any tendency to looseness of the bowels, even if seemingly innocent, should be promptly attended to by sending the patient to bed, and carefully regulating his diet. Chilling draughts should be avoided, and under no circumstances should patients be allowed to rise—a bed-pan being used when the bladder or bowels are to be evacuated.

The prognosis is especially grave when the attack is ushered in abruptly, with great irritability of the stomach and bowels, profuse depression, with painful cramps in the muscles of the legs and abdominal walls.

Dr. A. Herman[1] states that the detection of albumin, cylinders, and epithelium in the urine during the time of the precursory diarrhea is a sure sign that the case is one of cholera; otherwise the diarrhea is of other origin. The discovery of the comma-bacillus in the dejections will afford positive proof.

The treatment for this stage is usually as follows: If the case is tardy in onset, simple remedies are

[1] Allgem. Wien. med. Zeitschr., 1873.

usually efficacious, together with the directions already given as to rest and nursing. A combination of general and local stimulants, local sedatives, astringents, and stomachics has proved of benefit in the majority of cases.

A formula that has heretofore been much used and extolled is the so-called Asiatic tincture:

℞.—Chloroformi . . . . . f℥j.
Camphoræ . . . . . ℥ij.
Ft. sol. et adde
Sp. ætheris. co. . . . . f℥ij.
Tr. opii
Tr. capsici . . . . āā f℥ss —M.
Ol. caryophylli
S.—From five to fifty drops in water.

The following combination has been recommended by Dr. E. R. Squibb:

℞.—Tr. opii
Tr. camphoræ . . . āā f℥j.
Tr. capsici
Chloroformi (purified) . . . f℥iij.
Alcoholis (strong) . . q. s. ad f℥i.—M.
S.—A teaspoonful in water.

Dr. Alfred Stillé recommended for the precursory diarrhea a formula containing tincture of catechu, chalk mixture, and a small quantity of laudanum. Chlorodyne has been much used in this stage of the disease. Small doses of brandy with lime-water, frequently repeated, or, better, plain soda-water, sometimes control the vomiting. In this stage opium, with calomel or blue pill, has been recommended by many writers, to stimulate the biliary secretions. For local application, mustard plaster or mustard and chloroform sometimes allay the abdominal pains.

The second, or cold stage, or that of collapse. In this stage the patient is in great danger. The most prominent symptom is the constant discharge of sero-epithelial material from the stomach and bowels. This fluid is of a grayish or whitish color, serous, intermixed with fibrinous flakes, and is usually passed without effort, being sometimes ejected from the bowels and stomach simultaneously. In some cases there is a persistent hiccough and painful cramps in the muscles of the legs, arms, fingers and toes, and abdominal walls. The cramps are often attended with contraction of the extremities. The patient is weak, stupid, heavy; the eyes are dark and sunken; the conjunctivæ are dull, dry, and covered with a film; the tongue is dry and covered with a light, pasty film, and the nose is sharp and pinched.

The breath is icy cold, the respiration shallow, while the voice is husky and whispering. The skin is cold, blue, shrivelled, and bathed in a cold, clammy sweat. The extremities first become cold, and afterward the trunk. The urine is scanty or suppressed. The blood is deprived of its water, thereby becoming greatly decreased in bulk and thickened, so that the poor, weak heart cannot propel it to supply the thirsty and famished tissues. The patient grows weaker and passes into a state of unconsciousness, and death ensues. Treatment at this stage is usually followed by little apparent benefit.

The skin and mucous membranes are pouring out the fluid from the blood and tissues, so that they are in no condition to absorb medicines brought in contact with them. Medicines injected subcutaneously are scarcely absorbed, for osmosis is reversed. Intravenous and rectal injection of saline fluids has been used with varying results. The bowel would not be likely to absorb and the fluid would probably be rejected. The object of the saline injections is to make good the loss caused by the general leakage from the body. Transfusion of milk has been tried to the same end.

Dr. David B. Smith has proposed the injection into the veins of amyl nitrite, to overcome arterial muscular spasm. He injected into the veins of a patient two drams in thirty-five minutes without appreciable benefit.

A physician in India has recently published his experience with corrosive sublimate, which he employed in doses of $\frac{1}{100}$ grain.

Artificial heat and cutaneous stimulants have been used over and over again, with but little effect. If the patient survives the second stage, reaction slowly takes place. The treatment of the second stage is eminently unsatisfactory. The ability of the patient to tide over the crisis seems of more importance than the administration of medicaments.

The third stage, or stage of reaction, or stage of secondary fever. The conditions demanding treatment are extreme prostration, fever, and an alimentary canal deprived of its epithelium. The secretory activity of the kidneys is greatly impaired. The condition is decidedly typhoid. The plan of treatment will be expectant. One important point to be borne in mind is that the stomach and bowels will tolerate but little nourishment, for even after the patient has been convalescing for days a slight error in diet may induce a relapse.

I append a list of the medicines that have been employed in the treatment of cholera—

Mercury—Calomel, blue pill, and corrosive sublimate in small and frequently repeated doses. The first two are often combined with opium. These are given for the purpose of quieting the stomach and stimulating the natural secretions.

Tincture of camphor—Used as a systemic as well as a local sedative.

Tincture of capsicum—A stomachic and stimulant to the gastro-intestinal canal.

Opium.—Tincture and deodorized tincture as local and general sedatives. To be given in small doses. Morphine has been used hypodermatically.

Chloroform—Both as a stimulant and sedative, to allay gastric irritability.

Sulphuric Acid—A tonic, refrigerant, and astringent to the gastro-intestinal mucous membrane (and a germicide).

Nitric Acid has been employed by itself and in the form of Hope's mixture, a combination with tincture of opium and camphor-water.

Creasote—As an antiseptic, as well as to allay irritability of the gastro-intestinal mucous membrane.

Brandy is the favorite alcoholic remedy, used early in small doses, in combination with lime-water or plain soda-water. Champagne has been largely used to allay gastric irritability.

Turpentine has been administered as a stimulant.

Atropine acts as a stimulant to the respiratory and cardiac centers and diminishes secretion.

Amyl Nitrite has been tried in the hope that it would dilate the arterioles and subdue muscular spasm.

Arsenic has been extensively used to check the vomiting, small doses being used.

Phosphorus, copper salts, lead salts, strychnine, have also been administered.

22 S. EIGHTEENTH STREET.

CHOLERA AND ITS MIGRATIONS.

BY HENRY HARTSHORNE, M.D.,
OF PHILADELPHIA.

THE extreme public alarm existing in this country concerning cholera, and the action of municipal and national authorities in their endeavor to exclude it, have caused immense commercial losses and great inconvenience, indeed distress, to individuals and families. It seems important, therefore, that well-defined and well-sustained opinions on the subject should be held by physicians and sanitarians, to whom the people naturally and properly look for advice.

The intervals, often of a number of years, between the widely-prevalent epidemics of cholera, especially in this country, leave opportunity for many of the facts in their history to be practically forgotten. Of physicians now in practice, a large number did not have personal acquaintance with the visitation of 1866; few of them reach back in memory to those of 1849 and 1854. Moreover, the complexity of the subject of the causation of disease, particularly with regard to the questions of personal contagion, local infection, fomites, and atmospheric transmission, accounts for the diversity of opinion even amongst medical men; leaving the conclusions current from time to time often remote from the secure foundations of exact science.

Personal acquaintance, as a practitioner, with cholera in 1849, 1854, and 1866, as well as a good deal of attention to the literature of the subject,[1] makes it pardonable for me to recall at this time some of the facts, and the legitimate, indeed logically necessary, deductions from them, which appear to be now largely lost sight of, even within the medical profession. As astronomy was a science before Schiaparelli, so cholera had a history before Robert Koch. Yet certain ideas are now by many persons taken for granted, which were long ago tried and found wanting; some of them as far back as 1831–32. A few cardinal questions may serve to bring the matter clearly in view.

Is cholera personally contagious? Only one *rationale* of its personal transmission has taken much hold of the minds of the medical profession: that of its being produced by the use of drinking-water infected by the stools of cholera-patients. There is much to sustain the opposition of Pettenkofer and others to this theory; all the facts asserted in its favor being explicable under the wider generalization that, in the presence of the epidemic cause, foul drinking-water is the most effective of all agencies in the propagation of cholera. Since the discovery by Koch of the asserted specificity of the comma-bacillus, the cholera-stool theory, and with it the contagion-idea altogether, has prevailed over everything else; bringing back a *wave* of rage for rigid quarantine, isolation, etc., under which we are now suffering more than ever before in this country. It is satisfactory to read in the editorial columns of THE MEDICAL NEWS (September 3, 1892) an allusion to the "disputed question of the causal relation of the so-called comma-bacillus." The affirmation by T. R. Lewis, Ray Lankester, and others of the identity of that microbe with one commonly found in the intestines, and even in the saliva, has been denied but not disproved.

That the cholera-stool transmission cannot be the exclusive mode of extension of cholera over the world is demonstrated by well-known facts. Look, for instance, at the immense zigzag leaps, or rather flights, taken by the epidemic in its migrations after entering Europe from Asia.

In 1831 cholera was in Warsaw in April; in Hungary from May to September; in St. Petersburg in June; in Moscow in September; in Berlin and Vienna first in August; Hamburg, October 11th, and Sunderland, England, October 26th; but not in Edinburgh and Glasgow until January, nor in London till February, 1832; in Dublin and Paris in March. On our continent, Quebec and Montreal had it in June, and later in the same month New

[1] Cholera: Facts and Conclusions as to its Nature, Prevention, and Treatment. By Henry Hartshorne, A.M., M.D., etc. J. B. Lippincott & Co., Philadelphia, 1866.

York and Albany; Philadelphia in July; Boston and Baltimore in August; by September it was present, with more or less virulence, in twelve States of the Union.

Not proposing to touch upon this history, except for the purpose of exemplification, it may be mentioned that in 1849 the first American cities attacked were: In January, Memphis and St. Louis; in May, Chicago, Buffalo, New York, and Philadelphia; in July, Baltimore had a very remarkably limited epidemic, affecting *one-half of its almshouse building*, the side whose windows overlooked a large and foul cesspool. England and Wales, besides Cologne and other Continental cities, were affected with the epidemic in 1848–49.

In 1865, Arabia and Egypt were severely visited in the spring; Constantinople, in July; then it spread over Europe. In 1866 it was in Egypt in June; thence it traversed Europe, and finally crossed the Atlantic, reaching New York, Philadelphia, and some other cities; it was our last cholera-epidemic. Since that time the most notable cholera-year in Europe has been 1884. Its ravages during that summer were particularly severe in Naples, 1200 deaths resulting from it in that city by the middle of September, and nearly 11,000 altogether in Italy.

The order of succession in the European cities in the present year has been, so far: Moscow, St. Petersburg, Paris, Hamburg, Havre, and Antwerp. How did cholera pass from St. Petersburg to Paris without, so to speak, stopping at stations by the way? Political sympathy, it is true, exists between Russia and France. The Psychical Society might suggest that it was communicated by telepathy; but sanitary science admits no such conception. Neither should it hesitate to recognize that such a transit could not be checked by any quarantine or *cordon militaire*. The latter measure was fully tried in Europe as long ago as 1831–32, with absolute failure; at Vienna, for example.

An *instantia crucis* against the dependence of the migration of cholera upon transmission by the channels of human intercourse occurred in France in 1884. The outbreak at Marseilles and Toulon in June of that year was made the occasion of a scrutinizing investigation. There was then no cholera elsewhere nearer than India. The Chief of the Naval Bureau of Health and the Admiralty Inspector, Rochard, declared officially that the disease was not brought by any vessels from elsewhere.

Dr. Brouardel made a special visit of inquiry to the infected cities. His conclusion, as reported to the Académie de Médecine, was published in a letter from Paris to the *London Times*, July 4, 1884. It was to the effect that the two sailors first taken ill had not been to sea for five years, and had no communication with other vessels; and that the same was true of a person who died of cholera at the Lycée in Marseilles, June 21st, about a week after the two sailors were attacked. Brouardel affirmed decidedly that (notwithstanding a charge made against a vessel from China, all on board of it being well after a voyage of forty-five days) it was impossible for any vessel to have brought the infection to Marseilles and Toulon. Yet 5000 deaths occurred in France, mostly in those two cities, in June, July, and August, 1884.

In the *American Journal of the Medical Sciences*, July, 1873, Dr. E. M. Estrazulas presented important testimony showing that an epidemic of cholera beginning in Paraguay in 1866 and continuing as an endemic for three years, could not have been imported by human intercourse, by ships or otherwise; the peculiar circumstances of the war with Brazil making this impossible.

As to the possibility of the personal contagion of cholera in any other way than through the entrance of the stools into drinking-water, some facts, now generally forgotten, but on record, may be here recalled. Dr. Austin Flint well contrasted cholera, in this respect, with typhus, smallpox, and scarlet fever.[1] In Moscow,[2] in 1831, 587 patients affected with cholera were admitted into a hospital containing 860 patients of other kinds, yet not one of the latter took the disease. Dr. Alison,[3] of Edinburgh, testified that in 1832, and in 1848–9, the dissecting-rooms of his city were almost exclusively supplied with cholera-subjects; but in neither year was there a single case of the disease among the numerous students attending in those rooms. How preposterous, in view of such evidence, seems the assertion by cable, September 3, 1892, that a porter in Berlin was attacked with cholera half an hour after carrying to the disinfecting chamber some linen of a traveller just arrived from Hamburg! If that were so, how could any survive who handled all the linen and put it into the chambers for disinfection?

Dr. Foy[4] and ten others in Warsaw, in 1831, inoculated themselves with the blood of cholera-patients, tasted their dejections, and inhaled their breaths, without taking the disease. Similar experiments were performed, with the same negative result, by surgeons and medical students at Moscow and Dantzic in 1832, and afterward by Lizars, Coste, Schmidt, Meyer, Marshall, and others. Dr. Houston in the *Richmond Medical Journal*, in 1866, stated that a man in Wheeling, Va., lay all night in the clothes of another who had just died of cholera, without evil consequences. How unreasonable, then, is the *panic* that leads some persons

[1] Practice of Medicine, p. 425.
[2] Brigham: History of Cholera, p. 324.
[3] British and Foreign Med.-chirurg. Rev., Jan. 1854, p. 22.
[4] Gazette Médicale, 1831.

to be afraid, almost or quite, of the shadow of anyone who has been near a place, or a vessel, infected with cholera. We read the following in a recent cable despatch from Europe:

"Hamburgers are treated like lepers elsewhere in Germany. Hotel-doors are shut in their faces, and it is impossible for them to obtain lodgings. Many of them have been known to alight from the railroad trains a few stations before reaching Berlin, and to come into the city by local trains, in order to avoid inspection. The authorities are endeavoring to stop this practice, but find it difficult to do so."

Let us hope that no such inhumanity will throw discredit upon civilization in this country.

Some other facts in the history of cholera, strangely ignored by many, need to be here recalled. In 1848 two emigrant ships, the *New York* and *Swanton*, left Havre at a time when there was no cholera there, the former going to New York and the latter to New Orleans. Both were attacked by cholera during the voyage; one when sixteen and the other when twenty-seven days out at sea.[1] If there had been cholera at Havre when they started no chance of so long a time of incubation for the disease could possibly be allowed by any, either of the older or of the more recent authorities.

In 1854, two of the Copes' line of packets, sailing from Liverpool for Philadelphia, at a time when there was no cholera in the former city, were attacked by cholera when many days, one of them, the *Tonawanda*, two weeks, out at sea. The latter vessel, after the disease had continued for several days, neared a large iceberg, which reduced the temperature of the air 30°. On the day before the iceberg was met the largest number of cases occurred; after that, no new one at all; the morbific cause appeared to have been frozen out. In April, 1866, two steamers, the *England* and the *Virginia*, left Liverpool, the former for Halifax and the latter for New York. One had on board 1202 passengers, chiefly emigrants; the other 1043, of whom 1029 were in the steerage. There was no cholera in Liverpool at that time; but both vessels were attacked, one five days and the other seven days from port. In all of these instances now mentioned, the only rational explanation is that the epidemic cause *passed over the ocean through the atmosphere*, independently of human conveyance.

On account of this manner of migration I propose a new term as applicable to epidemic cholera. It is *autoplanatic* (from αὐτός, self, and πλανάω, to wander); that is, wandering under causal conditions peculiar to itself, as distinguished from the conveyance of smallpox, scarlet fever, measles, etc., only through human intercourse.

In view of the facts alluded to, and others also which are particularly familiar to those who have resided in British India, it is not strange that many of those most fully and closely acquainted with cholera are convinced of the uselessness of personal quarantine as a measure for its exclusion anywhere. That view of it has been emphatically affirmed by such eminent authorities as Gavin Milroy and Sir Joseph Fayrer, in England; Stewart Clark, Payne, Bryden, and Cunningham (after thirty-three years' residence), in India; Cazalas, in France; Pettenkofer, in Germany, and Tommasi-Crudelli, in Italy.

On the other hand, *sanitary police* (including, as properly coming under that term, Dr. Joseph Holt's systematic disinfection of infected or suspected vessels) has had signal triumphs, showing that it is entitled to entire confidence for the prevention of cholera, always and everywhere. Notable instances of this might, were space here allowed for it, be narrated as occurring in the arrest of a very destructive epidemic of cholera in 1884, in Genoa,[1] by a change from a bad to a good and pure water-supply for the city; a similar result at Mendoza,[2] in South America, in 1887, following the provision by the government of Buenos Ayres of means for boiling all the drinking-water used by the inhabitants of the infected town; and the eradication of an epidemic occurring for the third time on the island of Takasima, Japan,[3] in 1887, by a thorough system of sanitary improvement, under charge of a company having in its employ a large number of laborers on the island.

Shortening the time of detention at quarantine to three, four, or five days, sufficient for thorough disinfection of all suspected *fomites*, is a most beneficial improvement on the old time forty days' imprisonment on board or at a Lazaretto. This is in the direction of scientific as well as humane progress. There is room for further progress in the same direction. It is within the power of the medical profession at the present time to render a great service to commerce, as well as to philanthropy, by urging the immense advantage of thorough sanitary police over any and all measures of quarantine, in the certain and perpetual prevention of epidemic cholera.

Port Physician.—Dr. Henry Leffmann has resigned the position of physician to the Port of Philadelphia, and Dr. E. O. Shakespeare has been appointed by Governor Pattison as his successor.

RESULTS OF THE EMPLOYMENT OF TUBERCULIN AND ITS MODIFICATIONS AT THE ADIRONDACK COTTAGE SANITARIUM.[1]

BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, N. Y.

THE principal interest that attaches to the cases to which I am about to draw attention lies in the fact that both the main factors concerned in the causation and development of tuberculosis were treated at the same time — a change of climate, a systematic, restful open-air life, feeding, and hygiene being invoked to efface that nutritive vice which constitutes susceptibility, while at the same time a method said to exercise a specific curative influence upon the existing pathologic processes was regularly applied.

We must usually content ourselves with placing our patients amid the most favorable environment attainable, the beneficial influence of which is primarily aimed at the existing malnutrition, and secondarily at the diseased processes; but even if we succeed in arresting the progress of the malady by these means, and in improving nutrition, the patient still carries for a long time an infectious, though dormant element, ready, like a smouldering fire, to break out, and sooner or later, again overcome the newly-acquired resistance. The ideal plan of treatment in tuberculosis would, therefore, be one that would enable us, while improving our patient's general condition, to stamp out this infectious element within his tissues, and thus obtain a more permanent cure. Koch's method, perhaps more than any of the many hitherto proposed, gave promise of doing this, and, although its extravagant claims have not been sustained by experience, and it has fallen into general disuse, some investigators, prominent among whom may be mentioned Klebs and Hunter, have clung to the belief that tuberculin contains a remedial element; that many of its injurious substances may be eliminated, and that even if the exaggerated specific virtues claimed for it cannot be verified by experience, we may, by following Koch's suggestion, ultimately obtain a product free from the dangers of tuberculin, yet capable of instituting in tubercle reparative changes of greater or less degree, leading to cure. I have sought, by a brief study of these cases, to obtain a certain amount of evidence as to the efficacy and dangers of Koch's tuberculin when exhibited to patients living under the most favorable surroundings attainable, and also as to the relative curative value and dangers of the modifications proposed by Hunter.

Are we in the future to cast these bacterial products aside and rely entirely on favorable environment alone? and are our efforts to be directed solely to improving nutrition, as in the past, or may we yet hope that with an enlarged knowledge of these complex products and their effects, a substance may yet be produced, free from danger to the patient and capable of staying, to a greater or less degree, the ravages of a disease against which our best-directed efforts are at present too often of no avail?

Treatment with Koch's Tuberculin.

For the sake of brevity, only the main features of the cases treated with tuberculin and the results obtained will be stated. Thirteen patients were treated at the Sanitarium with Koch's tuberculin for an average period of eleven months. The longest treatment was carried on for eighteen months; the shortest for four. The injections were discontinued for about six weeks at intervals of from two to three months; the doses employed were usually small; constitutional disturbance, as indicated by a temperature above 100° F., being avoided if possible. As the doses became large, the intervals between the injections were lengthened.

Diminished susceptibility to tuberculin was observed in most patients, as the result of previous treatment. At whatever stage of the disease they were classed, the cases were selected as presenting some favorable features, though all showed the rational and physical signs of pulmonary tuberculosis, and their expectoration contained bacilli. Six were classed as incipient, four as advanced, and three as far advanced. The results were three apparently cured; in three the disease was arrested; three were improved, and four steadily failed. Of the six incipient cases, three were apparently cured; two had their disease arrested, and one was improved. Of the four advanced cases, two were finally classed as arrested, and two failed. Of the three far-advanced cases, two were improved and one failed. The average gain in weight for nine patients was thirteen and one-quarter pounds; the average loss for three patients, three and three-quarter pounds. The complications were tuberculous inflammation of the ankle-joint once; fistula-in-ano once; hemoptysis twice; inflamed non-suppurating cervical glands once, and fresh pulmonary involvement twice.

These results, even in selected cases, are, on the whole, but little better than are usually obtained by the climatic and out-of-door plan alone. They illustrate, however, that in cases in which the nutrition is constantly maintained at a high standard, more can be expected of tuberculin than in those in which the reverse holds good. The improvement that almost invariably follows the injections in apyretic cases, and is so encouraging to patient and

[1] Read at the Ninth Annual Meeting of the American Climatological Association, held at Richfield Springs, June 23, 24, and 25, 1892.

physician, does not seem to be continuous, but ceases before a cure is effected. The dangers incident to the injections are undoubtedly greatly lessened by the use at first of small doses, by close supervision of the invalid's habits, and by good climatic and hygienic surroundings. They are, nevertheless, real, and some of the complications seem to have resulted from the treatment. Nevertheless, my impression was that in many cases, for a time at least, a distinct and specifically beneficial effect was produced, not so much on the general condition of the patient as on the malady itself; unfortunately, the cases most suitable for this treatment are precisely those in which recovery may be hoped for under the more tedious but much safer climatic and out-of-door plan, but in at least some of these under observation the cure was apparently hastened by the injections. Koch's method is certainly the first proposed that, judged by the physical signs, can produce a specific impression on tubercle, even though this impression may, without any apparent reason, often ultimately tend to an aggravation rather than a cure of the disease. Its uncertainty in this respect is its greatest drawback, and is no doubt due to its being a mixture of good and evil, a combination of many elements, both remedial and injurious, as yet but little studied or understood. In acute cases, with high fever, it has seemed but to hasten the inevitable end. Even in its crude state, it has undoubtedly a really beneficial influence, and in the apyretic types it is, in skilled hands, capable of inciting reparative processes in tuberculous tissues, and of even turning the tide in favor of an ultimate arrest or cure of the disease. Its uncertainty of action and its very evident dangers have seemed to me, however, to outweigh its curative influence, and, until further research has opened the way to safer treatment by this method, our sole dependence must still be placed on a favorable environment, and our best efforts continue to be directed to a thorough application of all measures that improve nutrition.

The names of Klebs and Hunter are most prominently associated with the idea of eliminating from tuberculin some of its dangerous elements, while retaining its curative ones. Klebs has seen fit to surround his work with the mystery that has hovered over this product from its discovery, and has given no exact data that would as yet enable others to produce his tuberculocidin or test his conclusions. Hunter, on the other hand, has given his methods in such clear and concise terms that no difficulty is experienced by the bacteriologist in preparing the substance he recommends. As a result of his researches, he has proposed two modifications of Koch's tuberculin, designated as B and CB, both of which bring about in lupus certain reparative changes, tending to cure, but unaccompanied by fever, and each varying greatly in the character and intensity of the local reaction it produces. Following Hunter's directions explicity, I found no difficulty in preparing in my laboratory from tuberculin the modifications he has proposed, and a set of experiments in animals to test their relative value and dangers was at once undertaken. The results have been given in a paper[1] read recently before the Association of American Physicians, the conclusions reached being first, that CB contains much less of the remedial element than tuberculin, and is apparently quite as dangerous; second, that modification B is as efficacious as tuberculin, and free from some of its dangers. In view of this evidence the use of CB was discontinued at the Sanitarium, and modification B alone tested.

Treatment with Hunter's Modification B.

Ten patients were treated at the Sanitarium with injections of this substance, the longest period during which the treatment was continuously administered being six months; the shortest three weeks, the average about five months. Four cases were classed as incipient, three as advanced, and three as far advanced. Though these patients were all selected for some favorable feature in their malady, they all had pulmonary tuberculosis and bacilli in their expectoration. The results were four apparently cured, the bacillus having disappeared from the expectoration of all, though one still showed in his scanty sputum a few elastic fibers. All of these were incipient cases. Of the three advanced cases the disease was arrested in one; one was improved; one was unimproved. In the three far advanced, one was improved and two were unimproved. The average gain for eight patients was six and three-quarter pounds; the loss for two patients five and one-half pounds. The complications were fistula-in-ano once, and once a prostatic swelling that disappeared without suppurating. No new areas of disease were developed in the lungs, though it undoubtedly progressed in those who remained unimproved by the treatment.

These results, though limited to so few cases, are certainly encouraging, and are better than are usually obtained by climatic and hygienic treatment alone; and the disappearance of the bacillus, even though it should prove to be temporary, is a fact of some significance. The gain in weight was not as marked as might have been expected, but may, in a measure, be explained by the comparatively short duration of the treatment. The modified tuberculin was first given in doses of 0.3 gram daily, and slowly and steadily increased as long as no rise of temperature occurred. It was carried finally to 0.7 or 0.8 gram. No general reaction at all took place in

[1] THE MEDICAL NEWS, September 3, 1892.

apyretic cases, and the local reaction was less marked than that which occurred after injections of tuberculin. The latter was nevertheless very perceptible, and the changes brought about in the diseased areas were the same as occur more slowly during the spontaneous arrest and cure of tuberculous lesions by natural methods. In two of the feverish cases, nothing but an apparent aggravation of all of the symptoms resulted from the injections, and these were promptly discontinued. In the two others the temperature gradually fell and marked improvement occurred. To anyone familiar with the irregular course and relapsing nature of pulmonary tuberculosis it is quite evident that no conclusion of value as to any special treatment for this disease can be reached in a few months, but as far as such a limited experience can prove anything, I have been favorably impressed with the freedom from ordinary complications and with the excellent results produced in so short a time by injections of this modified tuberculin. More extended research and clearer knowledge of the various elements, both beneficial and injurious, contained in bacterial products, as well as of their effects upon tuberculous animals, may in the future lead to still further improvement in this as yet tentative method of treatment. Specific medication, to whatever degree of perfection it may yet attain, will necessarily best be applied in conjunction with climatic and hygienic measures. At present its limitation to early and nearly apyretic cases seems indicated.

Hunter and Klebs have confined their labors entirely to the products of the tubercle-bacillus as found in Koch's tuberculin, and Hunter has apparently been partially successful in already obtaining an improved substance that causes much less fever and is evidently much less likely to bring about an aggravation of the disease and dangerous complications. Kinnicutt's experience in the wards of St. Luke's Hospital, and my own observations bearing both on the climatic aspect of the question and on experimental tuberculosis in the laboratory, are in accord thus far and point to the advantages of Hunter's modification B over crude tuberculin. In view, however, of the very evident limitations of our chemical knowledge of the true nature of bacterial products it has seemed to me that the facts already gained by a chemical study of the subject might be supplemented by further animal experimentation with pure cultures, as they can be grown by any bacteriologist, and that some of the mystery that has so long clung to these products might, in a measure, be dissipated by determining, first, whether liquid cultures of the tubercle-bacillus contain a remedial element of sufficient efficacy to cure tuberculosis anywhere and in any animal; second, whether this substance is to be found in the bacilli themselves or in the culture-medium in which they have developed. In the paper already referred to, evidence has been offered showing, first, that liquid cultures contain a remedial substance with which I have been able to cure inoculation-tuberculosis in the rabbit's eye; second, that this remedial element is to be found in the beef-broth in which the microbes have been developed; third, that a glycerin-extract of bacilli, freed by washing from the culture-medium that clings to them, tends, in animals, to favor rather than retard the spread of the disease. These facts are significant and encouraging; they indicate the need of further research, and that we may entertain a reasonable hope that a substance which may prove of decided remedial value in human tuberculosis may yet be obtained from the various products formed in artificial culture-media by the growth of the tubercle-bacillus, and it would seem that, if Koch's suggestion has been called a "shot in the dark," it was, nevertheless, well directed by a skilful hand, and needs, perhaps, but the light which further research may yet bring to make it effectual.

MEDICAL PROGRESS.

Vasomotor Ataxia.—COHEN (*Polyclinic*, vol. 1, No. 2, p. 85) expresses the view that a group of affections, including exophthalmic goiter, local syncope, local asphyxia, symmetrical gangrene, angio-neurotic edema, urticaria, some forms of asthma, perhaps myxedema and other rare and curious affections characterized by hypertrophy or atrophy of the thyroid gland, may be comprehended in the generic designation of vasomotor ataxia. These affections present in common phenomena dependent upon vascular contraction or relaxation. In many of these conditions blood may be found in the urine, sometimes in large quantities, at other times detectable only by microscopic examination; or there may be subcutaneous extravasations of blood, or hemorrhages may take place from mucous surfaces.

Artificial Immunity to Cholera.—To determine if the removal of the virulence of cholera-bacilli treated with an extract of the thymus gland, with preservation of the power of conferring immunity, depended upon the exposure to heat in the process of preparation or upon the action solely of the thymus extract, BRIEGER and WASSERMANN (*Deutsche medicin. Wochenschr.*, No. 31, p. 701) added scrapings from agar cultures of cholera-bacilli to the thymus extract, which they placed upon ice for several days, and with the product they were likewise able to confer immunity.

Protracted Labor and a Fourteen-pound Infant.—HARRIS (*Lancet*, No. 3596, p. 256) has reported the case of a sextipara, in which pregnancy was estimated to have lasted for three hundred and twenty-five days, a still-born female child, weighing fourteen pounds and measuring twenty-seven inches in length, being delivered. The woman had previously borne two other children weighing more than twelve pounds each.

SATURDAY, SEPTEMBER 10, 1892.

CHOLERA.

THE cholera is at our doors. The duty of the hour is to see that it does not gain entrance. Rigorous measures have been taken to prevent an invasion; and the timely and energetic action of the national, State, and municipal authorities is deserving of the warmest commendation. The coöperation of our Canadian neighbors, also, must be received with much satisfaction, as without it we should be exposed to a risk that it would be difficult entirely to remove.

The battle is, however, by no means won. The enemy has but been repulsed. His ways are most devious and insidious; and he will surely pass the lines if vigilance be for a moment or in a degree relaxed. So many influences are at work that the health and civic authorities must be on their guard lest they be moved by sentimental or specious motives to deviate an iota from their position of rigid exclusion. The carriers of the disease-poison must be kept out, be they persons or apparel or baggage or freight.

Great pecuniary loss may be entailed upon commerce by the necessary measures to be adopted, but a community or a nation must protect the lives of its inhabitants at any sacrifice. Nor can the quarantine restrictions be withdrawn until for some time after the danger of disease-importation has subsided; and with the withdrawal of the more rigid restrictions must come a careful scrutiny that not an isolated case enter and be the possible focus of an epidemic, the limits of which might exceed conception—for the danger is not confined to the present. If it were, there need be little occasion for alarm—for the low temperature of winter would soon bring an epidemic at this season to an end. The greater danger lies in the locking up of the germ-cause of the disease, under favorable conditions of warmth and moisture, in clothing and baggage, to be set free at some opportune moment at a later day, to inaugurate a work of incalculable devastation.

The best treatment of cholera, as of all diseases, and from which the most certain results can be expected, consists in the prophylaxis. With the cause of the disease known and avoidable, cholera becomes a preventable disease.

At other parts of THE NEWS will be found indicated by competent authorities the means and measures to be adopted in the treatment of the various phases of an epidemic of cholera, while the masterly paper of SHAKESPEARE must carry with it the conviction of profound insight.

There can be no question that the regulation of quarantine and of all that pertains thereto should be under the control of the central Government, so that in times of need adequate and uniform measures of protection may be speedily adopted and put into systematic, active operation. Under existing conditions, carelessness or ignorance or parsimony on the part of any marine port may render nugatory the salutary effect of the greatest vigilance on the part of all other ports.

The impending danger will not have been without fruit if it shall lead to legislation centralizing and strengthening the hygienic arm of the Government, and clearly defining and liberally extending the powers of those to whom is entrusted the responsible duty of protecting sixty-five millions of people from the inroads of foreign disease.

What applies to the body politic holds for the individual. The keynote of health is prophylaxis. Each person in a community must consider himself the conservator of the public welfare. It becomes the duty of the physician in especial, particularly in times of epidemics, to impress upon his clients the necessity for the observance of the strictest precautions and the early treatment of what would ordinarily be considered slight ailments.

Let us realize the danger of an invasion of cholera; let us strengthen our protective fortifications; let us render the soil unsuitable for successful implantation; and let us be prepared to root out the evil should it make its appearance in our midst; but, above all, let us not create unnecessary alarm.

LOCAL QUARANTINE FACILITIES.

IF the impending danger of cholera serves to awaken a reasonable interest on the part of the citzens of Pennsylvania in the unsatisfactory nature of the local quarantine arrangements, it will not be an unmixed evil. While the Board of Health is to be commended for the efforts it has promptly made to provide for the emergency, it must be admitted that the putting of new wine into old bottles is but a poor policy.

The present quarantine station for the port of Philadelphia was established about the beginning of this century, largely under the fear of yellow fever, which at that period visited northern ports almost every summer. The arrangements, regulations, etc., were adapted to an age when steam and telegraphs were unknown. In the lapse of a century the facilities of the station have become inadequate and unsatisfactory It is now out of the ship-channel and in the center of a growing population. Residences and places of resort adjoin its bounds. The average draft of water at its landings is so small that most vessels cannot approach within hundreds of yards, and all transfers of passengers and baggage must be made by lighters.

Efficient quarantine of the present day requires facilities for rapidly and safely discharging vessels of heavy draft and for housing and treating passengers. To compel a large number of persons to remain in the steerage of steamers is to invite extension of disease, and is, in fact, a sanitary crime.

The detention of passengers involves the absolute prevention of escape, which can only be secured by their transfer to an island or hospital-ship. Such isolation is also essential for the prevention of the spread of infection, for a location on the mainland can never be wholly disconnected from the surrounding territory, and escapes or unauthorized exits or entrances may easily occur.

The Delaware River presents several points at which such island-quarantine could be located. The best sites are rather far down, but there is considerable advantage in having such a station so far from the city proper that visits to it are rather difficult.

An important feature which is lacking in the present station is the separation of the general administrative departments from the places in which diseased or suspected persons are housed. A combination of the two departments is highly objectionable. A large portion of the work of a quarantine officer is routine inspection, and there is no propriety in locating his office and the quarters of his subordinates on the same territory with the house of detention and hospital. Any convenient place along the shore where the ship-channel approaches within a reasonable distance and affords space for temporary anchorage will suffice for the location of all buildings not required for the detention or treatment of the sick or suspected.

The island station need not be located close to the administrative station. Vessels ordered to discharge passengers, sick or well, can proceed without difficulty some miles up or down the river and return to convenient anchorage when such discharge is accomplished. Discharges of cargo in quarantine can be made in lighters, if necessary.

THE TREATMENT OF TYPHOID FEVER.

UNFORTUNATELY, the treatment of typhoid fever is a subject of never-ending interest. When we consider that typhoid fever is, in every sense of the term, *preventable*, the word "lamentable" scarcely seems adequate to describe the condition of affairs permitting its prevalence. When, again, we think of the interest aroused by the doubtful reports of cures by Pasteurism of an affection so rare as hydrophobia is in Philadelphia, it does seem strange that the constant and unanimous testimony of physicians concerning the causation of typhoid fever in this city should so long fall upon unheeding ears.

If one were to compute only the annual money-value of the lives lost, the time subtracted from labor, the interruption to business, and the expense incidental to a prolonged sickness requiring assiduous nursing, more or less drug-shop stuff, and skilled medical attendance, the sum-total would be found to represent the interest upon a capital more than sufficient to provide the pure water and efficient drainage, to the absence of which the undue prevalence of typhoid fever in the city of Philadelphia must be ascribed.

As yet there is no specific treatment for typhoid fever. Possibly there may be discovered in the

blood-serum of convalescents an anti-typho-toxine. Until then the treatment must be one of rational empiricism. While it is true that in the majority of cases an "armed expectancy" seems justifiable, yet there is a large number of cases in which death must occur unless there be active interference with the progress of the disease. Such interference best takes the shape of systematic cold-bathing.

There is no longer any room to doubt the correctness of the claim made by BRAND and his followers that the disappointments and failures experienced by various observers are due to their departure from BRAND'S method. The patient must be bathed systematically—that is to say, every third hour so long as the temperature manifests a tendency to exceed 102.2° F. (according to BARUCH, 103° F. in the rectum). The bathing must be bathing—*i. e.* "tubbing"—and not something else. The entire body, except the head, must be immersed in water which about three-fourths fills a tub sufficiently long, sufficiently broad, and sufficiently deep for its purpose.

The cold water must be cold and not hot. If at first it is necessary to introduce the patient into a bath of a temperature above 65° F., it should nevertheless be rapidly reduced to that figure, and after the first two or three applications, it should be 65° F. at the time the patient enters it. An air-cushion may be suspended over the head of the tub, as a pillow, and a water-cushion ring be used to support the nates. Before being placed in the tub, the patient's face should be sponged with ice-water, and while in the tub cold affusions to the head and shoulders should be kept up. The entire body, except the lower half of the abdomen, must be subjected to friction during the time the patient remains in the water.

After coming from the bath, he should be received in a linen sheet resting upon a warm blanket and hot bottles should be applied to the feet. The sheet is brought around the body, and, in order to prevent contact of wet cutaneous surfaces, is tucked in between the lower extremities and between the body and the arms. Over this the blanket is wrapped. If the temperature has been over 103° F., the patient remains in the sheet for five or six minutes. Otherwise he is immediately dried with the sheet and then with soft towels. Sleep usually follows the bath.

A little alcohol, preferably as red wine, should be given just before and just after bathing.

No medicine should be given during the treatment, except when urgently indicated for a definite purpose, such as emptying the bowels or keeping up the elimination of urine. The diet should of course be simple, unirritating, and nourishing, milk being preferable to anything else. Many of Brand's followers, however, both in Europe and America, give semi-solid food. Indeed, the ability to digest such food is claimed as one of the good effects of the bathing.

For private patients or for hospital patients this treatment is the best, unless the patient comes under care so late in the second week that the powers of reaction are greatly lowered. Good judgment is then more than ever necessary, and as a rule graduated baths and packs are to be substituted. So, too, some patients, even among those seen early, do not react well, and the method must be modified accordingly. With increasing experience the exceptional cases become fewer.

The results obtained at the German Hospital of Philadelphia for many years by J. SOLIS-COHEN, who bathed only the more severe cases, and more recently at the same hospital by J. C. WILSON, TRAU, and WOLFF, who followed Brand more closely, and the results obtained by S. BARUCH in the Mount Sinai Hospital, of New York, are absolutely convincing that the same success can be obtained in America as in Germany, by equally consistent and resolute practice.

Antipyretic drugs, and especially those of the coal-tar series, should never be used in typhoid fever. To this statement there is no exception. They reduce the temperature at the expense of the recuperative powers of the patient, and when they do not kill, they delay recovery by their interference with metabolism and with excretion. As we have again and again pointed out, cold bathing is not only antithermic but antifebrile, and it is synergistic with the natural processes of recovery. It exerts a notable influence upon nervous disturbances. This was especially marked in a case recently under observation at the Philadelphia Hospital. Not only did wild delirium almost instantly cease when the patient was placed in the tub, but, although delirium returned in a mild form, yet whenever the patient reëntered the water his mind became clear and remained clear during the bath and for nearly an hour afterward. On being asked how he felt, he replied, "I feel good when I'm in the bath." This, too, was a case that came under observation

in the second week, and concerning the outcome of which a dubious prognosis had seemed necessary.

When for any reason cold-bathing is impossible, frequent cold sponging, ice-rubbing, the cold wet-pack, cool spraying, binding cold cloths upon the wrists, applying ice-bags to the head, chest, abdomen, enemata of ice-water, and various other methods of utilizing cold may be employed as more or less efficient substitutes. They cannot, however, fully replace the bath.

Under these circumstances intestinal antisepsis should be attempted by the judicious use of drugs, such as calomel, beta-naphthol, naphthalin, salol, creasote, guaiacol benzoate, guaiacol salicylate, bismuth salicylate, zinc sulpho-carbolate, and the like. Our preference is for salol and bismuth salicylate, if there be a tendency to diarrhea. When there is constipation calomel is used, together with beta-naphthol or salol.

When the indications for turpentine (dry, glazed, or brown tongue, with tympanites) are present, terpin hydrate is sometimes combined with salol. Turpentine can certainly be used to advantage, as taught by GEORGE B. WOOD and H. C. WOOD, not only in the condition mentioned, which occurs late in the second or early in the third week, but after defervescence, when convalescence is delayed and there persists a diarrhea attributed by G. B. WOOD to ulceration that has failed to heal.

Strychnine is sometimes useful, especially toward the third week, when the heart is becoming enfeebled. Alcohol also finds its place at about this time.

Water must be given to drink freely, and nurses should be specially instructed not to wait for the patient to ask for it. Insomnia and delirium, almost unknown when patients are systematically bathed, may in other cases be treated with opium, bromide, or, if need be, chloral. Hyoscine hydrobromate hypodermatically is sometimes useful.

Of complications, hemorrhage from the bowel is often unnecessarily alarming. The majority of cases recover. In treatment, milk-diet should be temporarily suspended and some such aliment as beef-juice, beef-tea, or peptones, that can be absorbed from the stomach, be administered. Opium, with or without tannic or gallic acid, should be given, to splint the bowel. Turpentine, if tolerated, may be given in comparatively large doses in light emulsion. Cold applications to the abdomen are often useful. If cold bathing has been practised, the bath should be discontinued for a time, in order to fulfil the indication for rest.

Among other conditions demanding suspension or cessation of the cold bath are collapse, pleurisy, pericarditis, severe laryngitis, threatening edema, bedsores, intestinal perforation, and peritonitis. Such complications are, however, rare in cases that are bathed. Albuminuria from infectious nephritis is usually benefited by the diuresis following the bath, and would not furnish a counter-indication, unless it give rise to large effusions or anasarca. Should perforation occur, operation may be thought of. To be successful it must be prompt. The indications, counter-indications, and technique will be discussed in a future article.

EXCISION OF THE MEMBRANA TYMPANI, AND REMOVAL OF THE TWO LARGEST AUDITORY OSSICLES.

THIS operation is performed in two varieties of aural disease, viz., in chronic purulent otitis media and in chronic non-purulent otitis media. The patient must be anesthetized in order to save him pain and keep him still. Illumination of the ear is then best obtained by light from a six-volt electric lamp held by a band on the surgeon's forehead.

What can be accomplished by this operation?

In chronic purulent otitis media, excision of the necrotic membrana and ossicula, and of the granulation-tissue always present in these cases, removes a large quantity of obstructive and septic matter from the drum-space, promotes thereby drainage, and permits more direct and complete antisepsis and asepsis of the suppurating tympanic cavity, thus entirely checking or greatly diminishing the purulent discharge from the ear. This operation also favors a renewal of the muco-periosteum of the wall of the tympanic space when this has become carious, and improves the hearing greatly in some cases, in consequence of the more direct entrance of sound-waves to the stapes in the oval window, brought about by the removal of the mechanical hindrances already named. Furthermore, excision in chronic purulent otitis media, by the removal of septic matter from the upper and back part of the drum-cavity, prevents mastoid necrosis, sinus-thrombosis, and cerebral abscess.

In chronic non-suppurative catarrh of the middle ear, the membrana tympani is thickened and, with the ossicula, is retracted, and sometimes it has become adherent to the promontory. Retraction of

the membrana and the malleus brings about retraction of the incus and stapes, and impaction of the latter in the oval window. In many instances there are evidences of adhesions between the ossicles and the surrounding tympanic walls. This condition in the membrana tympani and ankylotic ossicles causes seventy-five per cent. of all cases of so-called chronic catarrhal deafness, with its frequent attendants of tinnitus aurium and aural vertigo. Very often these symptoms continue unabated even after the most elaborate treatment of the naso-pharynx and Eustachian tube. By the excision of the membrana tympani and the two largest ossicles in such cases of chronic non-suppurative catarrh of the middle ear, the hearing is sometimes improved, especially if there is no restitution of the membrana; but the entire and permanent relief from tinnitus and aural vertigo afforded by the surgical removal of the thickened and retracted membrana and ankylotic ossicula, and the consequent release of the impacted stapes, constitutes one of the most brilliant achievements of modern aural surgery.

REVIEWS.

TRANSACTIONS OF THE EIGHTH ANNUAL MEETING OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION, held at Washington, D. C., September 22, 23, 24 and 25, 1891. 8vo, pp. xvi, 276. Philadelphia: W. B. Saunders, 1892.

ALTHOUGH the freshness of the papers contained in this volume has suffered by the long delay usual to the publication of society proceedings, and by the fact that many of the papers have already been published elsewhere, the collection is an interesting and valuable one. While climate is an element of consideration in most of the papers, it is not so in all. As a matter of fact, the larger number of papers are devoted to consideration of diseases principally involving the air-passages. Out of twenty-nine papers it would be difficult to select some for consideration without tacitly reflecting upon the others, and it would not be possible within the limits of this review to give even the titles of all of the papers. Suffice it to say that the volume as a whole is a representative one that reflects credit upon the body from which it emanates.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK, FOR THE YEAR 1892. 8vo, pp. vii, 540. Published by the Society. Philadelphia: Wm. J. Dornan, 1892.

OF the fifty papers and addresses contained in this volume, fourteen consider purely surgical subjects, while fifteen more consider topics partly gynecologic, partly surgical; four are ophthalmic; seven appertain to general medicine, including therapeutics and pathology; three deal with subjects related to the nervous system; and the remainder consider dermatologic and miscellaneous subjects. There are also obituary notices of deceased members; tables of officers, members, and county societies; rules of eligibility to membership; and an appendix containing laws of New York of interest to the medical profession enacted by the Legislature of 1892.

One will be struck by the large number of papers devoted to surgical subjects. Among these is a notable series that deals with the management of genito-urinary calculus.

Dr. Elsner contributes a report of an interesting case of typhoid fever in which perforation occurred, with adhesive and protective peritonitis, death taking place from intestinal hemorrhage. Dr. Martindale contributes a paper on diphtheria, in which he details the method employed in the treatment of twenty-three cases, of which twenty-two terminated favorably, recovery taking place in from five to twelve days after the treatment was inaugurated. The atmosphere of the sick-room was saturated with the vapors of equal parts of North Carolina tar and spirits of turpentine.

The volume is well and tastefully printed and bound.

THE RETROSPECT OF MEDICINE: A HALF-YEARLY JOURNAL CONTAINING A RETROSPECTIVE VIEW OF EVERY DISCOVERY AND PRACTICAL IMPROVEMENT IN THE MEDICAL SCIENCES. Edited by JAMES BRAITHWAITE, M.D. Lond., Obstetric Physician to the Leeds General Infirmary, etc. Vol. CV. January–June, 1892. Small 8vo, pp. xxii, 436. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited, 1892.

BRAITHWAITE has for fifty years furnished the profession in England and the United States an admirable summary of the best current medical literature. At the time of its first publication perhaps not more than two of our present weekly medical journals were in existence; now there are hundreds, and yet the *Retrospect* still holds its place. To survive against such odds is a severe test of merit.

The present volume maintains the reputation of its predecessors. The majority of the selections are from British writers, but a very fair representation is given to American writers, especially in the departments of surgery and gynecology, while in the Synopsis are to be found articles from German and French sources. Naturally the articles are very unequal in point of merit, but all are good, and taken together supply a large amount of valuable reading-matter.

THE MEDICAL AND DENTAL REGISTER-DIRECTORY AND INTELLIGENCER of Pennsylvania, New Jersey, and Delaware. Pp. 424. Philadelphia: George Keil, 1892.

This book contains lists of the National and State Medical and Dental Associations, with their officers and dates of meetings, of the Medical and Dental Colleges of the United States, Medical and Dental Laws, Hospitals, Homes, etc.; also the lists of Medical and Dental Practitioners, with their school and year of graduation, postoffice addresses, and office hours.

HYDROTHERAPY AT SARATOGA. A TREATISE ON NATURAL MINERAL WATERS. By J. A. IRWIN, M.A. Cambridge, A.M., M.D., Dublin, etc., pp. xv, 270. New York: Cassell Publishing Company, 1892.

THIS little book is devoted to a consideration of the therapeutic utility of mineral waters, and, as its name indicates, with especial reference to Saratoga. It is cleverly written and contains information that may prove both useful and interesting to the professional and the lay reader.

CORRESPONDENCE.

INTESTINAL DISORDERS OF INFANCY.

To the Editor of THE MEDICAL NEWS,

SIR: As intestinal diseases in children are now so common and cause so many deaths, permit me to give my experience in their treatment. Opium and the ordinary astringents I very seldom use, reserving them for the cases in which the discharges are so frequent and watery as to cause immediate danger. Creta preparata I seldom use, on account of its taste, and find that most cases do not need it. I bend my efforts toward restoring the discharges to their normal yellow, and find that in the vast majority of cases the diarrhea ceases of itself. If the milk curdles, if possible, I stop it temporarily or diminish the quantity, using, sometimes, lime-water. For food I prefer barley-water with white of egg and a little salt. I clear out the bowels with a mild laxative the first thing in most cases; then I give the following:

℞.—Pulv. acaciæ . . . . . ℥ij.
Glycerini . . . . . ℥ij.—M.
Ft. sol., adde
Bismuthi subcarb. . . . . ℥j.
Aquæ . . . . q. s. ad ℥ij.—M.
Sig.—A teaspoonful every 1, 2, or 3 hours, as needed.

This is sufficient for mild cases, and will soon get the passages yellow or brown. The bismuth is, of course, an astringent, but it is far more. It checks the formation of gas, is antiseptic, is tonic to stomach and bowels, and analgesic and alterative. I greatly prefer the subcarbonate, as it is much the lighter, free from grit, and pleasanter.

If the passages are too light-colored, the foregoing is not sufficient. It will then be necessary to add a little mercury in some form—*e. g.*, half a grain or one grain of calomel. In obstinate cases I have often seen this in twenty-four hours cause the passages to become normal. Having been a student at Bellevue, I was long deterred from using mercurials, since that great authority, Professor J. Lewis Smith, was opposed to them. Used for a few hours, I believe that, in some cases, they will do what nothing else will. I prefer calomel, as it is tasteless; gray powder is more likely to cause vomiting. I use no sugar. Ninety-nine babies out of one hundred will take the foregoing readily.

If the passages are green, watery, and foul-smelling, a single small dose of calomel (from ¼ gr. to 1 gr.), with the bismuth mixture later on, will, as a rule, quickly restore the passages to their normal condition. Elixir of vitriol in barley-water is useful for thirst, for hunger, as an astringent, and as a tonic. When the stomach is mainly at fault, I often add pepsin, etc. The hot-water bag is generally sufficient for the pain.

In very bad cases I stop all food, and give a decoction of logwood, with elixir of vitriol, for a number of hours, until the child is better. In cholera infantum I have with success used morphine hypodermatically. I think the acacia very important on account of its local sedative effect on the gastro-intestinal mucous membrane. Hence I use large doses of it.

I have not averaged one death a year for several years. Very respectfully yours,

H. M. HASKELL, M.D.

PALMER, MICH.

A CASE OF ATROPINE-POISONING WITHOUT DILATATION OF THE PUPILS.

To the Editor of THE MEDICAL NEWS,

SIR: I recently had a most unusual experience in the case of a woman who had been delivered of a dead child. On the morning of the second day she complained of great pain in the breasts, due to the secretion of milk. In order to check this secretion a solution of atropine (four grains) in rose water (one ounce) was ordered to be applied on lint to the breasts, and to remain on until the pupils responded or the mouth became parched.

After it had been on for two hours, the nurse made an examination and found the eyes normal. The mouth was somewhat dry, but the patient stated that it had been dry all morning, and that she thought nothing of that.

The woman fell into a quiet sleep, and, the nurse having been called out, she was not wakened.

In about four hours from the time of application, in the midst of a sound sleep, the patient awakened with a feeling of great oppression and difficulty of breathing, tingling and numbness in the fingers and arms, as well as in the toes and legs. The extremities were very cold and sweating profusely. The mouth was in the same condition as before. On the following day the solution was again applied, with a result like that of the previous day. On both occasions the pupils were found to be normal, and the tongue in about the same condition as before the application.

I report this case because I have never heard or read of any case of atropine-poisoning in which the pupils did not respond. Yours truly,

JAS. H. MCCARTNEY, M.D.

CHUNG KING, CHINA.

BELLADONNA PLASTERS FOR MASTITIS.

To the Editor of THE MEDICAL NEWS.

SIR: I wish to call attention to a simple and easy method of arresting threatened abscess of the breast in the case of nursing women. This consists in the application to the inflamed breast of an ordinary belladonna porous plaster. In the two years during which I have employed this means there has not been an instance in which the pain and swelling were not reduced in from one to two hours after the plaster was applied. Of course there is nothing new in the use of belladonna for this purpose; indeed, it is the drug generally first thought of; but the method of application is easier, neater, and

cleaner than the use of an ointment, and safer and more certain than solutions of atropine—at least such has been my experience. A year ago, for instance, in a case of marked mastitis, with active febrile reaction, I used an atropine solution for some hours without apparent effect. Then, as the danger of suppuration was growing imminent, I substituted the belladonna plaster, giving great relief in less than an hour. In this instance, as the baby had died, the plaster was allowed to remain on the breast until the secretion of milk had entirely ceased. In another case, a few weeks after, in which the child lived, I allowed the plaster to remain on just long enough to lessen the hardness and reduce the pain so that the mother could endure to have a breast-pump applied every two hours, until the baby, which for some reason now refused to touch that breast, had changed its mind.

NEWS ITEMS.

Sanitary and Preventive Measures.—The Philadelphia Board of Health has issued the following instructions:

Thorough ventilation of dwellings is essential to the health of the occupants. Fresh air is a most important means of promoting and sustaining the healthy action of the body. Personal cleanliness, and cleanliness about dwellings and premises, should be most carefully observed. A source of danger to health is the decomposition of organic matter in and about houses. Cellars, areas, drains, cesspools, should be examined to see that they contain nothing to poison the air. Privy wells should be kept free from garbage and refuse matter of all kinds, and if they have been neglected, immediate attention should be directed to them. Damp cellars are injurious to health. The foul and humid air from them will permeate the house, in spite of every effort to prevent it. A remedy should at once be instituted. It is common habit to throw waste material, especially kitchen garbage, into the gutters and streets, where it decomposes and vitiates the atmosphere. This is an offense alike unjust to ourselves and to our neighbors.

For the prevention of disease, a good nutritious diet and regular habits of life are indispensable; temperance in all things is to be observed; and avoidance of all excesses is strictly insisted upon. Constant vigilance is necessary to guard against the many causes which at this season of the year have a tendency to disturb the stomach and bowels, thereby depressing the nervous system and diminishing the power to resist disease.

CLEANLINESS is the essential preventive of disease. Keep your houses, cellars, yards, vaults, and sinks clean, wherever it can be done. Whitewash the walls of your houses, cellars, fences, outhouses, shops, factories, storehouses, and every other place about your premises where dampness exists, and where mould or mildew forms. It keeps the walls dry, sweet, and clean, and prevents the accumulation of moisture, which promotes putrefaction, through the presence of living organims, which are thought by many to be a specific cause of disease. Avoid all collection of coal-ashes mixed with kitchen garbage, slops, stagnant water, and other semi-solid or liquid filth, anywhere about your premises.

"Sewers, house-drains, waste-pipes, and water-closets should be frequently *flushed* with water—let on the largest practical volume. Water-closets and house-drains should be *flushed* in this manner every day."

VENTILATION.—Your premises, particularly sleeping apartments and cellars, should be thoroughly ventilated. Ventilation is no less a purifier than is water. It cleanses by oxidizing and drying. Keep your houses open and your windows raised during the day in good weather, that they may have the full benefit of sunlight and a free circulation of pure air. Avoid the possibility of exposure to sudden changes of weather at night. When the weather is cool or rainy, be sure to keep a fire in the house in order to prevent dampness; in sparsely settled neighborhoods, or in the suburbs of the city, have a fire in the house the entire season.

DISINFECTANTS are important. They absorb impure exhalations, prevent decomposition, and destroy noxious gases, but in no instance should they be considered or employed as substitutes for a pure atmosphere obtained by free ventilation. "These are simply aids in restoring and preserving healthful purity, and not substitutes for cleanliness and pure air."

They may be employed in cellars, yards, privies, vaults, sinks, water-closets, sick-rooms, bed-pans, stables, and in other places about your premises, or wherever practicable, when offensive odors are emitted.

Quicklime may be employed as a purifier, to act as a dryer in damp apartments, and upon moist and hurtful effluvia. It may be strewn as dry lime on the earth or placed upon plates, or, better still, in the shape of whitewash upon the walls. In the latter form, the addition of a small quantity of carbolic acid adds to its efficiency.

Charcoal is a powerful oxidizing agent. It may be used as a deodorant and purifier. "The sole condition necessary is the free access of atmospheric air, which the charcoal uses in oxidizing the putrid miasms." It should be freely strewn on the floors of cellars, and all places which may be damp and moldy. It should always be used in a crushed and fresh state.

An excellent deodorizing compound may be made by mixing *one part of peat charcoal, one part of quicklime, and four parts of sand or gravel.*

Sulphate of Iron (Green Copperas), Sulphate of Zinc, and Sulphate of Copper.—Dissolve one or two pounds of any of these salts in a gallon of water, and use the solution to correct decomposing and offensive matters. *Sulphate of iron* is the cheapest of these substances. Eight or ten pounds of it dissolved in five or six gallons of warm water, with one pint of crude carbolic acid added, makes *the cheapest and one of the best disinfecting fluids for common use* in privies, water-closets, drains, and sewers.

Before the emptying of privies or cess-pools the contents should be disinfected. For effective disinfection a solution of two pounds of *sulphate of iron* (*copperas*) in a gallon of water, or of one pint of liquid *chloride of zinc* in a gallon of water (to each of which two ounces of strong carbolic acid has been added) should be used in the proportion of one pint to each cubic foot of contents. After thorough disinfection a quantity of either of these solutions should be poured down daily to keep the cess-pits in good condition. *Chloride of lime* in the proportion of one pound to a gallon of water may also be used.

DISINFECTION PROPER.—*Fire.* The burning of infectious material, infected clothing, etc., is an effectual way of disposing of it. Articles of little value which have been soiled with infectious material (especially old clothing and bedding) had better be burned.

Heat. Boiling for half an hour will destroy all known disease-germs. This is the cheapest and best way of disinfecting clothing and articles which are not injured by the ordinary operations of the laundry. *Moist heat* (steam) at 230° F. destroys germs of all kinds, even the most resistant spores, in twenty minutes.

Sulphur fumigation is an excellent method of purification. Place the sulphur in an iron dish, supported upon bricks in a wash-tub containing a little water; set it on fire by hot coals or with the aid of a spoonful of alcohol. All doors, windows, and other openings should be closed, and allowed to remain so at least twelve hours; the room should then be opened and well ventilated. Two pounds of sulphur will be required for a room ten feet square (1000 cubic feet of space). The amount should be increased for larger rooms in the same proportion.

Chloride of lime is one of the cheapest and most efficient of disinfectants. For the purpose of correcting offensive matters, and for utensils, sinks, water-closets, drains, bed-pans, etc., it may be mixed with water in the proportion of one pound to one gallon. Infected bed and body linen, towels, etc., which cannot be immediately boiled, may be disinfected by immersion in a solution of chloride of lime in the proportion of two ounces to the gallon of water, and left for four hours.

Corrosive sublimate is a powerful disinfectant, but on account of its *highly poisonous* quality should be used with the greatest care. Dissolve in water in the proportion of two drams to the gallon, and add one dram of permanganate of potash to give color to the solution. Label it carefully—POISON. Use one pint of this solution for the disinfection of each discharge in cholera, typhoid fever, etc., or for vomited matters. Leave in vessel ten or fifteen minutes before throwing into cesspool or water-closet. It will injure lead pipes if used constantly; it should not be placed in metal receptacles.

Carbolic acid is very useful for disinfecting soiled clothing, discharges from the bowels, vomited matters, etc., and for the general purposes of disinfection. A wineglassful (two ounces) of the pure liquid, well mixed with a quart of warm water, may be used in night-vessels, water-closets, sinks, or for wetting a sheet to hang in the doorway of a sick chamber; from half a wineglassful to one quart of warm water, for washing furniture, walls, etc.; two ounces to the gallon of water, for clothing, etc. One pint of strong carbolic acid added to five gallons of warm water should be occasionally poured into sinks and drains leading into sewers. One ounce of the crystals mixed with four pounds of slaked lime forms a good powder for covering over offensive heaps of filth or refuse that it is impossible or unwise to remove. Liquid acid diluted with two thousand times its bulk may be used for street sprinkling. *Carbolic acid soap* may be used for the hands.

"It appears to be characteristic of *cholera*, not only of the disease in its developed and alarming form, but equally of the slightest diarrhea which the epidemic can produce, that *all matters which the patient discharges from his stomach and bowels are infective;* that the patient's power of infecting other persons is represented almost or quite exclusively by those discharges; that they are comparatively non-infective at the moment they are discharged, but afterward, when undergoing decomposition, acquire their maximum infective power; and that if *they be cast away without previous disinfection*, they impart their own infective quality to the excremental matters with which they mingle in filth-sodden earth, or in depositories and conduits of filth, and to the effluvia which those excremental matters evolve; that if the infective material, by leakage or soakage from drains or cesspools, or otherwise, gets access even in the smallest quantity, directly, or through porous soil, *to wells* or other sources of *drinking-water*, it can infect, in the most dangerous manner, very large volumes of water; that the infective influence of the choleraic discharges attaches to whatever bedding, clothing, and like things that have been imbued with them, and renders these things, if not disinfected, capable of spreading the disease."—*Chief Medical Officer of Great Britain.*

PERSONAL DUTIES.—Observe strict cleanliness in your person and clothing. Bathe daily, if you have the convenience. If not, wash freely with cold water every day.

Change your undergarments daily, or as frequently as your circumstances will admit.

Be moral, regular in your habits of life, meals, exercise, and sleep.

Be careful to dress comfortably for the season, avoid the night air as much as possible, and when thus exposed put on an extra garment, and do not go into the night air when in a state of perspiration.

Be careful to avoid the use of alcoholic drinks. Do not suppose that their use will prevent the occurrence of disease. On the other hand, those who indulge in the custom are always fair subjects for disease, and when attacked the intemperate are particularly in a condition to offer feeble resistance.

Live temperately, live regularly, avoid all excesses in eating crude, raw, and indigestible food, especially cabbage, salad, cucumbers, and unripe fruits.

The boiling of milk and all water used for drinking purposes is a necessity.

Partake of well-cooked beef and mutton, rice well boiled, and avoid pastry and laxative fruit.

Take your meals at regular seasons, neither abstaining too long at a time, nor indulging too frequently. An overloaded stomach is as much to be dreaded as an empty one.

Avoid bodily fatigue and mental exhaustion. Lead a calm and quiet life. Let all exciting causes be avoided. If you depress or impair the vital forces, it is prejudicial to health. By excitement or violent exercise you increase the susceptibility of the system to disease.

During the prevalence of cholera, do not neglect even the slightest diarrhea, no matter how painless at first.

Discussion on Cholera.—The subject of cholera will be discussed at the meeting of the County Medical Society, to be held on September 14th. Drs. Shakespeare, Lee, Tyson, Hare, and Coplin are announced as participants in the discussion.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXI. SATURDAY, SEPTEMBER 17, 1892. NO. 12.

ORIGINAL ARTICLES.

TUBERCULIN AND THE LIVING CELL:

An Inquiry as to How the One Aids the Other in the Fight Against Tuberculosis.[1]

BY CHARLES DENISON, A.M., M.D.,
OF DENVER, COLORADO.

THE wonderful discovery of the bacillus of tubercle had not been demonstrated a longer time than might be reasonably expected before its consequent —the specific cure of tuberculosis—was (it now appears, too hastily) given to the world by the same earnest student of nature, Robert Koch, of Berlin.

The history of these two great discoveries is interesting and familiar to every student of medical progress, and needs no repetition here. But what is most remarkable is the present attitude of the great mass of the medical profession toward this second discovery—tuberculin—now, nearly a year and a half after its having been given out for use in America. The failure of distinguished men in using the remedy, according to the rules laid down by its discoverer, seems to have led to a feeling almost universally hostile to its employment. Editorial comments in medical journals are sneering and derisive in tone; authors in sections of the American Medical Association refer to the "failure" of tuberculin as a positive conclusion; and writers in medical periodicals continue, as of yore, to pronounce the edicts of their own conclusion—that there is no such thing as a specific for tuberculosis.

A few weeks ago an Associated Press despatch went the rounds that a certain Dr. A. M. Brown had announced in a medical meeting in Cincinnati that Professor Koch had acknowledged to him personally that "tuberculin was a failure." Knowing that the statement must be false, I wrote to Professor Koch, and have just lately received his reply. It gives me great pleasure to be able to refute such a slander of one who is doing so much for his fellow-men. Dr. Koch writes me that neither he nor his assistants know Dr. A. M. Brown, of Cincinnati, who, however, like others, may have visited the laboratory. His statement that "much of his time was spent in the laboratory of Professor Koch is false, and when he says that I have told him that tuberculin is a failure he states an impertinent fabrication." Professor Koch goes on to say that he has "the same belief in tuberculin as in the beginning. If it is used in the early stages of tuberculosis it will be highly useful." His experience is that this effect is a cure, or *Heilung*. "It is essential to discover the disease in time, which is best done with this material. To any one," Koch concludes, "who has ever spoken to me about it, I have never made any different assertion than the foregoing."

To the great majority of persons one of the most convincing modes of argument that can be used with reference to tuberculin is to deride the physician who would give his patient a remedy that he would not take himself. To a logically disposed and naturally suspicious layman this assumptive argument is conclusive, and the fearful idea seems to find a favorable culture-field, not only among laymen, but among professional men, because of the incomplete knowledge of Nature's laws and the undeveloped state of bacteriologic science.

A considerable experience with tuberculin during the past fifteen months, under conditions well calculated to enable one to judge of its peculiar and best effects, warrants me in saying that I would not hesitate to employ the remedy in my own case if I should again find myself tuberculous and be convinced of its need, as I have been convinced in the cases in which I have used it. This so-called "failure" of Koch's lymph has not been essentially in tuberculin, but rather in the inability of the medical mind to comprehend the method and the conditions requisite for its success. Nevertheless, the *receiving* medical practitioner, especially if he be handicapped by incompetency, should not be compelled to bear the blame that belongs chiefly to the *giving* originator of such a theory. Let me here say, that in criticising the rules promulgated when this new method of treatment was given to the medical profession I do not wish even to seem to detract from the renown due to the great discoverer. It is glory enough for one man to have illuminated the dark regions of the etiology of tuberculosis, and to have set the medical world thinking and working as has Professor Koch.

However, a different application of Koch's discovery seems to be positively demanded, so that sources of error may be eliminated and a successful line of action be marked out for the largest possible number of medical men.

It was my own belief from the commencement

[1] Read at the Ninth Annual Meeting of the American Climatological Association, held at Richfield Springs, June 22, 23, and 24, 1892.

that all of Koch's rules for the use of tuberculin were tentative, and that only in the crucible of time and experience could it be determined what rules would be confirmed and for what ones substitution must be made. I believe I owe my own success largely to my independent mode of procedure. For instance, I commenced with smaller doses, took more time for the treatment than Koch recommended, opposed the confinement of patients, and insisted on regular and systematic out-door exercise.[1]

It is not my intention to detail minutely the physical condition and course of treatment of the forty-eight cases (which include all up to June 1st) in which I have employed tuberculin. A paper on "Tuberculin," read at the last annual meeting of the Colorado State Medical Society, contains a report of my first twenty cases. The results in five of these forty-eight cases properly ought not enter into the final conclusion, for to them tuberculin (from 1 to 5 milligrams) was given only for diagnostic purposes. Two of these five are dead; in them the diagnostic effect of the tuberculin showed the utter uselessness of any effort whatever to check the destructive process. Of the remaining forty-three cases, I know of only four that have died. One of these died of measles a month after the last treatment (mentioned in the previous report referred to). Another case, of laryngeal tuberculosis, with a large cavity in the lung, died four months after a short course. Another died at his Canadian home, of extensive involvement of the lungs, five or six months after cessation of treatment; and a fourth, much improved, though with considerable excavation, died suddenly with pulmonary hemorrhage a year after taking a partial course.

All the cases (twenty-three in number) in which the dose of thirty milligrams or over was reached are now living and furnish good illustrations of the value of the treatment. Undoubtedly some of these, as well as others in which the treatment has not been concluded, will sooner or later die of tuberculosis, for already one or two have given up the fight, both as to healthful living and treatment, because of indifference or such natural results as exhaustion or lung-contractions, with circulatory or respiratory embarrassment.

Yet, on the whole, the results have been good enough, especially for the thirteen cases classified as finished or cured, and I cannot see how anyone cognizant of the serious lesions existing could hope for better.

The following table gives a classification of these cases, all having pulmonary tuberculosis; one also had lupus; in all but three the sputum contained bacilli previously to treatment with tuberculin.

TABLE.

Total number of cases	48	
Average age at commencement	30½	years.
Number of males	31	
Number of females	17	
Number in first stage of the disease—infiltration (or bronchial)	15	
Number in second stage of the disease—softening (or catarrhal)	3	
Number in third stage of the disease—excavation	30	
Excavation as large or larger in area than a hen's egg in	13	cases.
Excavation or large bronchiectasis on both sides in	3	"
Excavation, small and on one side, in	17	"
The largest dose of tuberculin (two milligrams or less) was used in	3	"
From 2 to 10 milligrams was reached in	10	"
From 10 to 30 " "	12	"
From 30 to 50 " "	3	"
From 50 to 100 " "	13	"
Over 100 " "	7	"
Both lungs were affected in	42	"
Only one lung was affected in	6	"
Uncompleted cases, including some yet under treatment, with good results so far as they have gone	13	
Graduated (finished) cases at an average dose of 80 milligrams	13	
Average time these were under treatment	3½	months.

The thirty-five unfinished cases, including all of the others, were under treatment for an average length of two months. In ten, the most advanced in treatment of the unfinished cases, the average dose reached was 83½ milligrams; these were under treatment for four months. These ten, with a few cases perhaps wrongly included in the finished list, include the tolerant or partly healed cases with cavities, the dismissal of whom, to my mind, is yet questionable; that is, as to the time when that would be safe. The time when the bacilli will all be cleared out is necessarily uncertain, because some of them are always quite sure to be retained in a cavity beyond the time required for them to multiply. The remainder of the unfinished cases, including those in which tuberculin was used for diagnostic purposes only, twenty-five in number, were under treatment, on an average, over a month; the maximum dose averaged 10 milligrams. There are also included eight or ten that left off the treatment for various causes (see my former report, referred to, for examples), as well as a number of cases doing well, but still under treatment or taking what I call a midway rest in the course.

In only eight are the results recorded as unfavorable, chiefly on account of physical or diseased con-

[1] A suitable method for the recording of temperature, pulse, respiration, etc., by the patient himself was also a part of my plan, together with devising a new antiseptic hypodermatic syringe for giving tuberculin. The latter, Tiemann & Co., of New York, have made for me, having milligrams marked on one side of the barrel and minims on the other, and with an adjustable piston-head, constantly fed with oil from a reservoir in the piston-rod to prevent shrinkage and make it work easily. These, with the individualizing of each patient, and the discovery of the stethoscopic signs of reaction to tuberculin, have proved to be valuable aids to the success of the treatment.

ditions. This latter class includes some or all of four diagnostic cases recorded as too acute or too generally infected for treatment with tuberculin. The good general condition of those dismissed previously to six months ago speaks better for the permanency of the effects than I had anticipated. It is an open question yet, however, when a person once tuberculous is absolutely free from taint—that time alone can determine.

Among the important questions to be considered is:

The modus operandi of tuberculin in tuberculous tissues.

In my report on this subject to the Colorado State Medical Society last year, I advanced a theory of the action of tuberculin which I much wish bacteriologists would either refute or more fully elucidate than, so far as I am aware, has yet been done. This theory or explanation was based upon the power of living cells to repair injuries to themselves independently of other parts of our body. This idea not only recognizes the power of the tissues to reproduce their like, but also indicates an independent thought of Nature that takes some cognizance of the extent of the injury and the quality of the injuring agent. The directness with which the hypodermatically introduced antitoxine of tuberculosis, or whatever else it is in tuberculin that constitutes its active principle, goes to the highly susceptible tuberculously affected tissue and there stimulates a healing process, is strongly suggestive, if not proof-positive that there is a natural susceptibility of those affected cells, because they are thus diseased. This effort in the direction of healing is an exaggeration of any attempt at repair previously made—a function involving purpose and selection, not heretofore attributed to the ultimate divisions of the living body.

Histologists do not appear to have yet fully comprehended these functions of the living cell; yet some of us practical physicians are convinced, both by experience and by analogy, of certain specific effects of tuberculin, and invite biologists, histologists, and bacteriologists to explain the facts and physical evidences upon which our conviction is based. Is the demand unreasonable? The histologists can describe, as Richard Garnet, of London, has nicely done, what connective-tissue cells are; how, as nucleated corpuscles, they variously lie in a matrix, through the interstices or minute channels of which granular or wandering cells freely pass, on missions of supposed utility, and in which spaces the lymphatics find their terminal ramifications—all of which suggest an intimate relation between the lymphatic system, the white corpuscles of the blood, and the connective-tissue cells—in other words, the means of repair or the fibrous healing-process. Yet neither this histologist nor any other can tell any better than you or I how the life-principle in these cells enables them to change their form, to increase their number, and to exhibit a power of choice and self-direction of action according to the various demands made upon them, such as is observed in a higher order of living beings.

It may be that this contemplation of the living cell, rather than the great complexity of minute forces—the animal body—will bring us nearer to the desired solution of the mystery of *life*. It is only nearer, however; the goal is not reached. Here, in the living cell, followed down to the minutest subdivisions of which a powerful lens will allow us to judge, is *life*, existing separately and independently, as well as in combinations. These associations are either harmonious or in controversy with other microscopic existences. Here, in the region of the living cell, is waged an incessant, many-sided warfare between living *constructive* and equally living *destructive* cells, compared with which, as numbers go, the wars of nations are as nothing; and there is no cessation until either the allotted end of life of all these cells is reached, or is anticipated by the death of the individual.

As to any difficulty others may have in accepting my explanation of the special action of tuberculin on the living cell, if study and reflection have the same effect upon their minds as they have had upon mine, the operation will grow in simplicity and naturalness. It is quite possible, I will admit, that my own vision is influenced by the *fibroid* glasses through which I am inclined to look, in the explanation of Nature's choice of the healing process in the arrest of chronic pulmonary phthisis. This view is based upon the observation of nearly 4000 cases, under climatic and other conditions, which have shown a greater amount of Nature's reparative processes than I believe has been shown by any like collection of similar invalids. Besides, is it not best, if possible, to explain these intricate effects upon natural grounds? For instance, is it not preferable to hold the theory that the formation of vomicæ in the lungs, of anal fistulæ, of rectal ulcers, etc., in the tuberculous are corrective excreting processes, rather than meaningless diseased foci, not to mention the natural efforts at elimination as indicated by septic chills and fever, odorous perspiration and colliquative diarrhea? We look upon these as the outward expressions of an inward warfare between the myriads of bacilli and the greater or less number of living cells.

The explanation given seems to me to be on the same line with the recent efforts among distinguished German experimenters, Ehrlich, Kitasato, and others, to find in animals a natural opposing element to toxic principles. Their success in fixing upon the juice of the thymus and lymphatic glands

as attenuating or neutralizing the toxic principles of typhus, diphtheria, tetanus, etc., is to me a wonderful discovery, not so very unlike that of vaccination for smallpox; yet showing that the animal system is by Nature furnished with the means, could we only discover them, to combat "every ill that flesh is heir to."

Then if, as is true, the known and appreciated effects, in tuberculous tissue, of tuberculin when rightly administered differ very little from the natural processes of cure to which the profession has all along been trusting, that harmony of action is a good guide to be governed by. Physicians have always tried, and I fear they always will, to assume the credit that rightly belongs to a patient through an unrecognized *vis medicatrix naturæ*. One cannot intelligently and fairly compare the excellent descriptions of cured lesions in tuberculous lungs, in persons dying of other diseases (so well described in a paper lately read before the New York Academy of Medicine by Dr. H. P. Loomis), with the known effects of contraction in affected lung-tissue and shrinking of cavities due to the action of tuberculin, and not feel convinced that the two processes are so similar as to be practically alike—a natural method of healing.

For the purpose of a minuter description of the treatment with tuberculin I will divide the effects into three divisions: first, external, at the point of injection; second, general or systemic; third, internal lung-reactions. That no confusion with other kinds of reaction to tuberculin may be possible, I will confine this part of the description to the third division, or the *local effects* in tuberculous lung-tissues, and to the principal physical signs by which they are recognized. I will also separate the third division into three subdivisions: (1) hyperemia, (2) congestion, (3) necrosis. These are not stages, as in the progress of a disease like pneumonia, but different results due either to the size of the dose or to the susceptibility of the patient.

The first effect, that of *hyperemia* of the affected lung-tissue, is to be looked for in cases in which there exists moderate susceptibility, with encapsulated bacilli or slight tuberculous infiltration, or more advanced conditions if there be a response to very small doses of tuberculin. There is probably an increased flow of blood to the affected part, and also an attraction of leukocytes, as shown in the experiments of T. Mitchell Prudden, who found that when dead bacilli are injected into living tissue, the white blood-cells are attracted in great numbers to the point. The same thing happens if the bacilli are alive, according to Dr. Bennet S. Beach, of New York. Here is to be found the process of elongation of these attracted cells, and their conversion into connective-tissue elements for the ultimate purpose of strangulating or suffocating the imprisoned bacilli. This is sufficient, if kept up, to do more than simply arrest the tuberculous process. It inaugurates a cure.

The physical signs of this reactionary effect, as I think I was the first to point out in my last year's report, consist mainly in *a harsh, puerile, or an exaggerated broncho-vesicular breath-sound*, as heard with the stethoscope over the affected or reactionary area. This is an exaggeration of what was heard before the tuberculin reaction, or it is heard in localities in which the breath-sound was previously inaudible or entirely different. It is not an evanescent effect, but usually continues, though in a lessened or lessening degree, during the whole course of treatment.

The second division of the reaction to tuberculin, that of local *congestion*, is an exaggeration of the first effect, to the extent of more or less local inflammatory engorgement. The greater swarming of the leukocytes and constructive or defensive cells to the infected areas may be so marked as to somewhat impede the circulation of blood therein, and dyspnea will be caused, with or without an exalted or depressed state of the nervous system—a feverish exhilaration or perhaps a fear of impending suffocation or harm. Sometimes there is even slight hemoptysis. Now, the process of elimination, under certain conditions, is indicated by the local appearance of moist râles, which more or less obscure the usually dry condition characteristic of the reaction to tuberculin in the affected tissue. It is here that the danger of reinfection may threaten if these moist râles are found in inefficiently ventilated portions of the lung. If the pyrexia is high, and appears late, especially if it is prolonged at a high point on the following day, the indication of a septic state (which may be the ushering in of a necrotic process in a tuberculous area) is so strong that the greatest caution must be exercised lest the destruction of the most affected spot occur. Previously to this, with or without the advent of moist râles, there is likely to be an increase of expectoration, with increased throwing off of dead, or dead and live, bacilli. This is followed by a decided lessening of expectoration as well as of the contained bacilli. Percussion does not afford nearly as much information as does auscultation. However, if from imperfect lung-ventilation, with or without the presence of moist râles, an occluded region is made known by an increase of dulness on percussion, an increased resonance is quite sure to follow the opening up of the affected lung afterward, and the appearance of the drying and contracting stage, which is the expected later beneficial effect of tuberculin.

The third and worst effect of tuberculin is *necrosis*, which I claim should always be avoided if possible.

The increased number of cells and cell-elements that crowd around the tuberculous nodules, or into and around affected areas, furnish a new, highly inflammatory substance, largely composed of giant or nucleated cells. By the multiplication and breaking down of these the circulation is shut off on the one side, the tuberculous tissue being on the other; the result is death of that tissue, or *necrosis*. The enemy and the containing tissue have both been destroyed together in the general shrinkage and sloughing that have thus been inaugurated. An enormous number of bacilli may then be thrown off in the sputum, which may also contain elastic fibers, shreds of lung-tissue, and pus-cells.

Meantime, Nature's effort at repair, if possible, corresponds with the extent of the injury in the affected area, and her process of infiltration and fibrous contraction is inaugurated, which may be the cure of the patient so far as that affected spot is concerned. However, the risk and shock to the individual, the deprivation of breathing-space, or involvement of other tissues, may be too great, and a more conservative and waiting plan of treatment ought to be followed. It should be borne in mind that all three of these degrees of effects may exist at the same time in different parts of the same lung.

The success of treatment with tuberculin rests upon many precautions, or upon favorable conditions to be secured by the physician in charge. Among these are: 1. The proper selection of cases. 2. As thorough a knowledge as possible of the physical condition. 3. The natural resistance of the tissue. 4. The intensity and extent of the tuberculous infection; and 5. The gradation of the dose.

The selection of cases suitable for treatment with tuberculin is a most important consideration. It is by exclusion of unfavorable conditions that mistakes are to be avoided. Besides, here in Colorado, I do not think it necessary to subject patients to this additional trouble, anxiety, and expense, who are so slightly affected and otherwise so well suited to the climatic cure, that they are likely to recover anyway. So it happens that I have refused or decided not to employ tuberculin in treatment in probably twice as many cases as those in which I have employed it.

An important consideration is the ventilation of the affected lung. For, if it be true, as the experimenters state, that in culture-experiments five or six days elapse before tubercle-bacilli begin to be reproduced, then when the bacilli are squeezed or carried out from the tissues into the lung-spaces or bronchial tract they must be removed by expectoration before the expiration of that time, or reinfection will occur. It would be better to leave the bacilli encapsulated than not to get rid of them when they are set free. If the action of tuberculin is expected to take place around the root of the lung or large bronchial tubes, the regions beyond may become convenient receptacles for the infectious tuberculous exudates when the contracting or healing process occurs in response to tuberculin. Thus, this question of lung-ventilation is, to my mind, second to no other, and it is a consideration that, it will be acknowledged, gives a great advantage to us who practise in Colorado, where the air is from a sixth to a third rarefied.

Now, the question of ventilation, together with the extent and nature of the infection and its results, fibroid or otherwise, can be so well determined that a thorough diagnostician can have confidence in his decisions as to the use of tuberculin. In addition to the usual proofs of a careful physical examination, strengthened by the clinical history of the case and the microscopic examination of the sputum, much direct information is to be gained by the use of the spirometer and manometer, in conjunction with the measurements of the respiratory movements of the right and left sides of the thorax respectively. The manometer gives the air-pressure that the air-cells will stand, and in a measure indicates the elastic tension, or amount of fibroid or connective-tissue healing that exists; while the spirometer tells the actual capacity of the lungs, which ought to be nearly in an inverse ratio to the amount of fibroid deposit, and also to the extent of the usually accompanying pleuritic adhesions. The rule that I have formulated for determining the respective ventilations of the two lungs (right and left), and which I always mentally follow in my own examinations, is as follows:

Suppose the normal spirometric record of a patient is only one half of what it should be for his height, and the expansions of the two sides are as one to two, then, if no defect or disease is noted in the better lung, it is well to assume that the lack of ventilation in the other lung is almost complete—that is, the half that is done is nearly all due to the good lung. For other variations in the bilateral measurements this rule can be correspondingly altered.

When it happens, as a result of the reaction to tuberculin, that the ventilation of a lung is defective, then, besides temporarily discontinuing the injections, there are mechanical means that will be sufficient to open up and clear out the suffocated regions. Among these are the use of the lung-compressor or emphysema-jacket,[1] the pneumatic cabinet, massage of the chest, horseback riding, and systematic

[1] This is an instrument I have lately devised for promoting the elasticity in overstretched and suffocated air-spaces, which, with my own spirometer and a new manometer that I have lately completed, Messrs. Truax, Greene & Co., of Chicago, are preparing to put on the market.

arm-exercise in the open air. I do not fear the result of this advice to take moderate and systematic exercise, for I have previously taken the precaution in these cases to determine that Nature has already commenced, through the fibroid process, to strengthen the affected tissues; and I have always refused (except for diagnostic purposes) to give tuberculin, unless the patient could come to my office. I long ago gave up the idea of keeping these patients penned up in a single building or sanitarium, as has been the custom in Germany. In Denver they spend much of the time on the splendid system of rapid-transit lines that radiate in all directions to the suburbs, and some have lived in adjoining towns, and come to the city for treatment from every two to five days, as directed. I am aware that in emphasizing the importance of exercise I am liable to clash with the views of many members of this Society. Several papers have been read the tone of which seems to me unnecessarily fearful of the results of exercise. A discussion of the question of "Rest in the Treatment of Consumption," at Colorado Springs, reported not long since in the *Climatologist*, appeared to be so one-sided as to give the impression that there was no opposition whatever among that excellent group of physicians to such a stand-still policy. In the use of tuberculin it will never do. I would rather run the risk of over-action, or even hemorrhage from exercise, than, because of the lack of it, allow the dead or live bacilli to remain and reinfect the system.

Another important point to decide before commencing injections of tuberculin is that there exists *only* the fever of tuberculosis, and not, in addition, the septic-pyemic fever that attends the breaking-down of lung-tissue and the extensive caseation of tubercles. There is no reason to expect tuberculin to do any good in this second form of fever, but, on the contrary, aggravation of the previously existing septic state might naturally be expected, for, as Klebs, of Zurich, in a letter lately received, expresses it: "You will also have fever by the introduction of pyrogenic substances from out the destroyed bacilli; but this fever is very well supported, and will cease if all or the greater number of the bacilli are destroyed." The want of an appreciation of this fact may be at the bottom of the fear that so largely pervades the medical mind—*i. e.*, a suspicion that tuberculin contains proteid substances that will themselves cause the septic fever.

I believe that this fear is unwarranted, and springs from the non-recognition of the previously existing septic state; in other words, tuberculin is a better diagnostician than its too suspicious professional critic. The natural result of this state of affairs is the demand that an effort be made to eliminate these harmful ingredients, supposed to be contained in tuberculin. Consequently, the chemistry of the extract is minutely gone into, and, according to Klebs, by treating it with platinum chloride, and filtering through alcohol, the alkaloid and harmful ingredients are thought to be separated, and the albuminoids, supposed to contain all the active healing principle, are saved, and finally constitute two and a half per cent. of the original tuberculin. I have not yet used any of this "tuberculocidin" of Klebs, nor Hunter's similar modification of tuberculin, for I do not need them, as I do not hold the same belief as they do as to the necessity of their procedures, and further, because I have a better guide than the usual fever-range, in the stethoscopic signs of reaction to tuberculin. Besides, Klebs's results with his tuberculocidin are no better than, if as good as, my own with tuberculin.

Dr. Libbertz writes me that tuberculin has been made constantly uniform from the commencement. Though the results in Dr. Kinnicutt's[1] cases, treated with Hunter's modification, were in the main favorable, I can make no use of them, because a constant stated dose was given at regular intervals, which is quite different from my plan—*i. e.*, the gradually increasing dosage for a given desired effect. I wish that we knew more about the composition of tuberculin and the chemistry of these substances proposed as substitutes. As the case now stands, I am rather inclined to agree with Koch, who says that much of the active principle of tuberculin goes through the dialyzer in making Hunter's modification, and, therefore, I conclude that both Hunter and Klebs are using a much diluted tuberculin—just as they ought to do, anyway.

Dr. Klebs claims that his tuberculocidin has an effect additional to that of tuberculin, in that it kills the tubercle-bacilli. The claim cannot be allowed, because others (Dr. Beach, of New York, for instance) have found the same destroying influence to belong to tuberculin, the proportion of the dead bacilli thrown off in sputum being variously estimated up to over 80 per cent. of the whole number. If Koch's extract exerts an injurious septic influence, certainly a patient of mine who has taken the injections for more than a year ought to have shown it by this time. This is a case of laryngeal tuberculosis in the third stage, fully reported in the *University Medical Magazine* for March, 1892. I gave him 180 milligrams on the Sunday before I left home. He always asks for a large dose as he comes on his weekly visit, saying that he feels better if he perceives some appreciable effect of the injection.

After all, perhaps, it is not strange that a fear of the consequences should generally exist among medical men, when we consider that the destructive

[1] New York Medical Record, May 21, 1892.

process of pus-formation and the constructive process of repair—connective-tissue growth—are so near each other, both originating in different degrees of inflammation under varying conditions. This thought grows in importance if it be considered that tuberculin, if given as Koch first directed, to produce necrosis, may favor this destructive process—as it will if given in too large doses, while, if given in smaller and appropriate doses, the effect will be constructive, with a return to a state of health.

The influence that tuberculin may have upon these processes is most interesting. The question has been raised by Prof. W. T. Councilman[1] whether or not the fibrinous exudation in the alveoli around the tubercle or in its neighborhood is a part of the tuberculous process? He considers that it is, because bacilli are found in this contiguous inflammatory tissue. Why should we not rather look at it as the natural reparative process excited by the central tuberculosis, the purpose of the fibroid process being the limitation of this destructive tendency? At the same time we will admit that the extension of tuberculous infection may be temporarily favored by the stasis of blood in this border-ground of the contest that is going on. In tubercles with centers undergoing caseation the fibrous tissue seems to be antagonistic to caseation—*i. e.*, the more there is of the one, the less there is of the other; sometimes a caseous mass resulting, and sometimes a fibrous nodule with a shrivelled nucleus at its center. In these nodules Cornil and Ranvier found blood vessels, and rightly reasoned that in them, and not in the caseous nodules without vessels, the cells retain their vitality to resist the tuberculous process. Is it not quite possible that tuberculin acts as a special stimulant to these fighting cells, and that the decidedly diagnostic sign of the commencing fibroid process under treatment with tuberculin is proof that both blood-circulation and connective-tissue formation are advancing into the lines of the enemy—*i. e.*, the tuberculous stronghold?

Councilman says that the tubercle-bacilli are taken into the tissues from the communicating air-spaces by the white corpuscles, and Koch also claims that these white corpuscles are changed into epithelioid cells by the action of the bacilli contained in them. If this is so, why is it not reasonable to infer that the process of cure is the reverse of the foregoing—*i. e.*, that the contracting influence under the reactions of tuberculin leads to the breaking up and subdivision of these giant and epithelioid cells? These, the natural homes or protecting envelopes of the bacilli, after subdivision and still bearing their bacilli with them, become the exudative cells, which sometimes crowd the air-spaces in the region presenting a local reaction to tuberculin. I have noticed that this connective-tissue increase, the most prominent feature of the healing process that takes place in connection with the employment of tuberculin, is likely to be accompanied with or preceded by an increase in this exudation. Does it not appear reasonable that this stage in the effect of tuberculin should be known and watched by the attending physician with the greatest care and caution!

Dr. Armand Ruffer, of the British Institute of Preventive Medicine, has lately asserted that it is the poisons excreted in the tissues by infectious microörganisms that attract the leukocytes to battle with the germs, and that the reason that in certain virulent cases this attraction is lost and the work of the defending leukocytes is ineffectual or feeble, is that these toxic principles are too generally distributed in the system—*i. e.*, in the blood-current, as well as localized in the tissues. Dr. Sternberg, of the U. S. Army, calls attention to the fact that Tizzoni and Centanni, experimenting upon infected guinea-pigs with Koch's lymph, stated that recovery is due to the development of an antitoxine that neutralizes the tuberculous virus. They seem to conclude that the antitoxine is developed in the tissues in consequence of the injection. Whether this is so, or if the antitoxine already exists in the tuberculin, as it is more reasonable to believe, further observation will have to decide. The influence is certainly specific upon tuberculous tissue. I could illustrate this by showing the gradual shrinkage of tuberculous glands on the side of the neck in a young woman among the unfinished cases in my list.

I have conceived the idea that perhaps the nodules that we have been accustomed to call tubercles are simply Nature's prison-vaults for the incarceration of the offensive bacilli; and, until someone proves the contrary, I shall not cease to suspect that the bacilli, when thus imprisoned, are deprived of nutriment for growth, or, perhaps, by pressure are prevented from multiplying, and that this perfected imprisonment constitutes the completeness of the state of "arrest" of pulmonary tuberculosis, whether by climate or otherwise, as heretofore accepted by the medical profession. Even more, the *policeman* function of the leukocytes, "the free lances of the body," may yet be shown to include the arrest of these bacillary intruders and detention within their own bodies until, having the power to do so, they can call to their aid those constructive and repairing carpenters—the connective-tissue cells—to build about themselves and their captured bacilli the strongholds intended for their permanent imprisonment.

If the foregoing figure is a reasonable representa-

[1] Article on "Tuberculosis," in Reference Handbook of the Medical Sciences.

tion of this inward struggle constantly going on in many of the human race, how very like a punishment for any future sins of omission or commission on the part of the tuberculous patient, as to the laws of healthful living, is the escape and multiplication in the body of these convict bacilli when once the resistance of the tissues is relaxed from lack of nutrition or nerve-support.

The difference is so great between tuberculosis in arrest, with the natural resistance of the tissues everywhere able to maintain their integrity, and tuberculosis of the lungs under full headway, with the living cells deprived of their power of successful resistance, as only to be faintly imagined by one thinking of the computations of bacteriologists. They compute that in this latter condition over twenty-one million bacilli are thrown off in the sputum of an individual each twenty-four hours, or fifteen thousand per minute. I do not know enough of the methods of division or growth of these germs to compute how many millions of bacilli yet remain in such a body, but this I do know, that that remedy must be a true specific for tuberculosis which bids so fair as tuberculin does to forestall such havoc, and not only aids in the arrest of the tuberculosis, but also supports the living cell in the supreme effort to eradicate the cause from the body. In view of the comparative failure of the usual internal antiseptic treatment of pulmonary tuberculosis by trying to saturate the system with supposed blood-purifiers, or the endeavors to reach the enemy by the use of germicidal inhalants, the physician of the future must come to the rescue of the living cell. In its fight against tuberculosis he will find, in rightly selected cases, the *antitoxine of tuberculin* an unrivalled aid to the best combination of climatic attributes, with sunshine, elevation, and dryness in the foreground, so that with every other attainable aid added, integrity and health may be preserved to the living cell.

PREVENTIVE MEASURES FOR THE INDIVIDUAL DURING TIMES OF ACTUAL OR THREATENED PREVALENCE OF CHOLERA.[1]

BY E. O. SHAKESPEARE, M.D.,
OF PHILADELPHIA.

I HAVE recently advanced elsewhere[2] some reasons why "the General Government should be supreme in the control of quarantine at all our frontiers," in the effort to keep cholera out of this country. I do not contend that State or municipal quarantine should be abandoned. On the contrary, even with the establishment of an efficient and judicious general quarantine as an outer line of defence and protection to the *general welfare*, provided and maintained at the expense of, and controlled by, the General Government, without exaction of port-fees, the local, State, or municipal quarantine can well serve an extremely useful purpose as a powerful adjunct in protecting the health of the locality against the introduction and dissemination of infectious diseases, and may be supported as in the present manner. What I now urge, and have earnestly advocated, is that, for the protection of the *general welfare*, for which Congress, in the same article of the Constitution that grants it power to guard the country from the attacks of a common enemy and the invasion of a foreign foe is authorized to provide, the General Government, especially in such a dangerous juncture as the present, should be active, provident, vigilant, and supreme.

I am requested by the Directors of the Philadelphia County Medical Society to express my views concerning the question of "preventive measures for the individual during times of actual or threatened prevalence of cholera," and I cheerfully respond, as any other physician would, prompted by the hope of rendering some useful service to my fellow-citizens.

As the purpose of this communication is, to a great part, for popular instruction, I shall avoid as much as possible entering into detailed arguments and the discussion of abstruse theories, limiting myself mainly to an orderly arrangement of conclusions, well established, based upon the evidences to be found in my recent *Report on Cholera in Europe and India*, and in other publications relating to cholera that have appeared in various parts of the world since 1883.

In my opinion, Asiatic cholera, highly infectious and frightfully mortal as it usually is when it obtains a foothold amid ignorance, poverty, and squalor, is, fortunately—even in such a favorite locality—of all the dangerous epidemic diseases the most easily and certainly avoided by the individual, if only the proper precautions be constantly and scrupulously observed. Cholera-victims may be lived with, handled, nursed and treated, with absolute impunity if these *precautions be never once forgotten or neglected.* The cholera-poison does not infect the air even of the sick-room; it cannot be inspired with the breath; it does not enter through the skin, or through cuts, sores, or abrasions of the body. It enters through the stomach only, and assails by way of the intestinal canal.

In the human being it is in the intestinal canal only that this infectious material multiplies enormously, sometimes with extreme rapidity, generating a chemical poison that attacks and destroys the lining of the epithelium of the intestines—caus-

[2] THE MEDICAL NEWS, September 10, 1892.

ing extensive flakes of the latter to be thrown off, while the raw surface thus exposed exudes great quantities of the fluids of the blood, constituting together the so-called rice-water discharges, frequently so rapid and copious—and which meanwhile is thence absorbed into the system, to play a formidable rôle in a direct and vicious attack upon the kidneys, heart, and nervous system. This infectious principle has been proved to be the so-called cholera-bacillus—an extremely minute vegetable parasite that multiplies in enormous numbers and with incalculable rapidity in the intestinal canal of the victim. Every drop of the evacuation of the bowels and of the stomach of a person who is suffering with Asiatic cholera contains thousands of these infectious parasites. These discharges and everything soiled or contaminated by them are therefore highly infectious and very dangerous. Cholera is never generated by fright, ill-health or constitutional weakness, filth, starvation, or anything else, unless this infectious principle be first introduced into the stomach. Without the actual presence and multiplication of the cholera-bacillus in the intestinal canal, an attack of Asiatic cholera cannot occur.

What, then, are the rational and reliable "preventive measures for the individual during times of actual or threatened prevalence of cholera?" They are crystallized in four words—*prompt isolation; thorough disinfection.*

Inasmuch as the safety not only of the health and of the trade of the locality and its immediate surroundings are involved, but also of a great State, and sometimes of nations in communication with it, are seriously threatened by the escape and spread of the infectious principle elaborated in and discharged from the intestines of the person suffering from an attack of Asiatic cholera, skilful and *constant attendance* is imperatively called for, and *should be provided at the public expense.*

Furthermore, that same public has a paramount interest and absolute right to be *assured* that every rational precaution against the spread and dissemination of the infectious agent be scrupulously and conscientiously enforced. This is tantamount to saying that the care of the attacked and of the dwelling, as well as the custody or close surveillance of all persons associated or in communication with him or it, should be under the strict control and direction of the jeopardized public, *through its own intelligent and responsible agents.*

The prevention of the spread of infection—of such enormous importance to the public—should, under no circumstances whatever, be entrusted in any degree to the ignorance or carelessness or conflicting interests of the inmates of the infected dwelling; neither should it be left to the chance of uncertainty through the incompetence or neglect or whimsical notions or personal interests or lack of authority of the private physician. Of course this means temporary invasion of the private rights and restriction of the personal liberty of a few individuals—whose own security, however, is thereby enhanced—but the public safety demands a temporary sacrifice of private rights under these circumstances, and there should be no hesitation or vacillation in requiring it.

I do not mean to say by this that the family physician called in attendance by the sufferer should be excluded from the performance of his private duties; on the contrary, he should feel, in his capacity as an individual guardian of the interests of the public health confided to his care, that he also should be prompt and careful in the discharge of duty to his patient, and he should at the same time keenly appreciate his relations as well to the inmates of the threatened household as also to the general public. One of the first things which the family physician should do in the discovery of a patient who is suffering with symptoms that warrant any suspicion that the case may be either a commencing or a fully developed attack of Asiatic cholera is that, immediately he leaves the house, he should promptly send notification to the Board of Health, without any delay whatever.

So long as there are in the town or city threatened *only a few scattered cases of the disease*, the most strenuous efforts should be made to prevent the establishment even of a localized epidemic. The daily work of the private physician, if he be sufficiently watchful for the discovery of such scattered cases, will be a great adjunct to the efforts made by public health-officers in stamping out the infection before there is any chance that it may spread throughout the community.

Under the circumstances surrounding us at present, with cholera in the port of New York and the possibility of its arrival by any ship proceeding from Europe with emigrants on board, there is no little danger, as experience has so often proved, that the infectious germs may escape quarantine-inspection, and proceed with the ship's inhabitants, released from quarantine, to their ultimate destinations, and produce there the commencement of an epidemic.

It is a well-known fact that looseness of the bowels and other disturbances of the digestive apparatus very frequently precede the onset of an attack of cholera. Such cases should be regarded with suspicion and be promptly remedied. When the onset is so well marked as to leave little doubt in the minds of the experienced of its infectious nature, of course the most careless physician will act vigorously. On the other hand, attacks of so-called cholera-morbus are not infrequent, especially during the summer

and early fall months, among persons who are addicted to imprudences of any sort, especially of injudicious eating and drinking. These attacks are particularly likely to occur among immigrants who, for the first time in their lives, indulge in copious drafts of ice-water, eat ice-cream, green corn, and other such articles of food and drink.

I cannot too earnestly urge upon the medical profession the great importance of unusual watchfulness at this time for undue bowel-disturbances, especially for attacks of so-called cholera-morbus, particularly when they occur in persons recently landed from emigrant ships. An attack of what seems like cholera-morbus among this class of people should be invariably looked upon with suspicion, and in every such case the precautions should be taken of thorough disinfection of stools and prompt isolation of the patient until the real nature of the attack shall have been determined.

In connection with cholera-morbus, I may say that there is most indisputable authority for the assertion that the *clinical symptoms alone* are incapable of furnishing to the most skilful diagnostician living reliable evidence upon which he can speedily determine whether a case in charge is one of Asiatic cholera or of simple non-infectious cholera-morbus.

From the time that Malgaigne went to Warsaw, in 1832, to make the acquaintance of an unknown plague in Europe, until Dr. Robert Koch, in 1883, visited Egypt and India to investigate the same disease, many have been the eminent physicians who have left their homes to study cholera in distant regions, and many have been the exhaustive observations of the disease in all of its forms and characters which have been made by the most distinguished clinicians and pathologists of the world during the times when it has repeatedly ravaged their own lands. The whole category of symptoms and visible signs by which Asiatic cholera under its various guises manifests its presence had been so often the object of the keenest and most intelligent examination, and so frequently the subject of most learned disquisitions, that its prompt and unhesitating recognition might reasonably seem, when it appeared in Europe in 1884 and 1885, to have been a matter of no great difficulty.

But what is the truth? Look at the recent experience of France, and Spain, and Italy, in 1884 and 1885. In each the prompt, vigorous, and judicious action required for the extinguishment of the spark before it could burst into an uncontrollable conflagration was paralyzed by doubt and uncertainty concerning the real nature of the disease.

While epidemic cholera was surely planting itself in France in 1884, few physicians asserted its presence with firmness, while the many denied it most positively. To remove the hesitation which this conflict of opinion naturally engendered, Drs. Brouardel and Proust were commissioned by the French Government to report upon the nature of the doubtful disease at Toulon. Those experienced physicians had the knowledge and the courage to unhesitatingly pronounce it epidemic cholera, but unfortunately they were unable to state its origin. On the other hand, Dr. Fauvel, Inspector-general of Hygiene, placed the weight of his high authority against that opinion, and reproached the commissioners with having uselessly alarmed the country and caused great damage to the commerce of France. Later, the National Consulting Committee of Hygiene officially declared that the disease was not Asiatic cholera, but was a benign cholera, non-contagious, and produced by local causes, and that it had nothing to do with importation from without, and possessed no power of epidemic dissemination. Added to these misleading statements was the impression produced by the majority of the medical press of that country in industriously supporting the assumption that the epidemic would limit itself to the locality of its outbreak, and would soon cease.

This history has repeated itself in the various declarations, official and private, concerning the nature of the present epidemic in Paris and its suburbs. The same may be said of the development period of cholera now at Havre, Antwerp, and Hamburg.

As in France, similar doubt and uncertainty and inaction existed in Spain at the commencement of the invasion of cholera in 1885. It is true that a few scattering cases of cholera, mainly confined to some localities in the province of Alicante, had appeared in 1884, but the epidemic which so frightfully ravaged Spain in 1885 undoubtedly spread from the town of Játiva, in the adjoining province of Valencia. After having lingered in that vicinity through the winter under the mask of *suspicious cases*, during the fourth week in March of that year the epidemic raised its head in that town. Public rumor to this effect, originating with the physicians of Játiva, soon reached the Governor of the province and the city of Valencia; and in response to the demands of the populace a special commissioner was dispatched to investigate. Arrived in Játiva, a few cases examined, and a hasty consultation held with the local board of health, an official declaration was hurriedly published that Asiatic cholera did not exist in that place; and later the provincial board of health confirmed this opinion. Nevertheless, the unknown mysterious disease continued to spread throughout the town, and, besides, rapidly invaded village after village, unchecked by any active opposition. Notwithstanding, as late as the 15th of April, the same provincial board of health formally congratulated the people upon the favorable course and slight importance of the disease, which was

even then officially looked upon as *only suspicious*. During this time of inaction and hesitation on the part of the authorities, there reigned the greatest anarchy of opinion among the local physicians. A few affirmed their belief that they were dealing with genuine Asiatic cholera; some insisted that the suspicious visitor was nothing more than the common sporadic cholera; others declared it to be a pernicious fever of choleraic type; many claimed that it was malignant malarial fever; yet others held that it was a kind of entero-gastritis; and not a few pretended that it was the bubonic plague, but without the boils. The whole history of the invasion of Egypt in the first place, and of France, Italy, and Spain later, is nothing but a repetition of similar doubts on the part of the physicians having to deal with the disease, and of inaction on the part of the local authorities whose business it was to adopt and enforce measures to stamp it out.

But why continue longer in narration of this disgraceful and unfortunate history of the doubts and contradictions and vacillations concerning the nature of the disease which have characterized that as well as all former visitations of Europe by epidemic cholera? It forcibly illustrates one most important fact.

That fact is, *unless the investigations of the German commission have brought to light in the presence of the cholera-bacillus a sure and unmistakable diagnostic sign of Asiatic cholera which can be quickly distinguished*, in spite of the great and valuable knowledge of the disease gained by the study of former epidemics, *we do not at present know how to recognize genuine Asiatic cholera in time to safely guard the people against its deadly power*.

In Egypt and in France and in Spain and in Italy the character of the disease and the consequent danger were not fully recognized until it was too late to arrest its destructive course, and thus it has been everywhere and at all times in the history of the march of epidemic cholera.

Fortunately for mankind, the observations and experience of the last nine years have at last placed at the disposal of the medical profession and of public health-officers most positive means of recognizing in a reasonably short time the infectious nature of the discharges of a suspected person by means of bacteriologic examination. The health-authorities should *invariably*—and the private physician whenever possible—resort without delay to this certain means of diagnosis in *every suspicious case*, and the suspected persons should be kept in strict isolation and surveillance until the results of such an examination be obtained. It is only in this manner that a population can be insured against the establishment of an epidemic following the appearance of scattered cases of choleraic diarrhea and masked cholera, which, because of their lightness, may escape notice, or because of their similarity to other diseases may be mistaken for the latter. Let every physician, therefore, regard it as a part of his duty to the general public to vastly supplement the watchfulness of the health-officials in the effort to detect and isolate at the earliest possible moment the *few scattered cases* which almost invariably precede the establishment of a widespread epidemic of Asiatic cholera. Let no misplaced regard for the tender sensibilities or vigorous protests of his patients or of their friends induce him at such a time to attempt concealment or delay, in the hope that the attack may ultimately prove to be void of the dreaded character. There is reason to believe that the awful calamity which has befallen the city of Hamburg is traceable to the criminal neglect of a single man. Let every physician, therefore, fully appreciate the importance of his responsibility to the general public. Besides alertness in the discovery and promptness in reporting suspicious cases, the physician could perform a great public service by notifying the health-department of nuisances and defective plumbing, drainage, etc.

INDIVIDUAL MEASURES OF PREVENTION.

Means and Mode of Infection.—Since the infectious agent exists in the evacuations both from the stomach and from the bowels, various materials become capable of conveying the infection of this disease—such as clothing soiled with this matter; hands fouled with it; articles of food and drink which have been contaminated with it. It is by means of soiled clothing and personal effects, upon which this agent is preserved in a more or less moist condition, that the infectious principle is usually conveyed long distances, both by land and by sea. The contamination of watercourses and small streams by vomit or dejecta is perhaps the most frequent and certainly the most rapid means of producing a sudden and widely-extended outbreak of Asiatic cholera. The watercourses are not infrequently also contaminated by washing therein the personal effects of cholera-patients.

Regarding the comma-bacillus of Koch as the infectious agent, it has been established by numerous and exact experiments that this microbe is not only able to live for a considerable length of time in water, but is even capable of enormous multiplication therein, especially if the water contain a certain amount of organic or vegetable material. The use of such contaminated water for drinking, bathing, and culinary purposes is perhaps the most frequent mode of introduction into the human organism of the contagious principle of cholera infectiosa.

The universal practice of the watering of milk also renders this article exceedingly and especially

dangerous to children during periods of the prevalence of cholera; and, where extensive and sudden local outbreaks of the disease cannot be attributed directly to the use of contaminated water, it is generally the milk which conveys the cause of infection. Other articles of food are in a far less degree liable to contamination, but there are numerous examples of infection occasioned by thoughtless and accidental contamination of vegetables, fruits, and other nutritive material.

Experience has abundantly proved two laws which have an important bearing upon the spread of cholera: (1) *The tendency to infection varies exceedingly among individuals, and is with the majority small.* (2) *Disturbed conditions of the digestive apparatus greatly increase the susceptibility of an individual and render him far more liable to an attack after exposure to the infection.*

As has already been said, it is exceedingly improbable that the infectious principle is ever conveyed to the healthy by the medium of the air; it is certainly never transported to any considerable distance in this manner. It is very doubtful, if even possible, that infection may take place through the lungs. It is certain that it cannot be effected by cutaneous absorption. The disease, therefore, cannot be properly termed truly contagious in the common use of that word. It is extremely doubtful if there be a single well-authenticated case upon record in which the disease has been conveyed in any other manner than by the introduction of the infectious principle into the stomach.

Still, regarding the comma-bacillus of Koch as the infecting agent, it has been abundantly proved that the normal acid juices of the stomach are capable of destroying it. It is, therefore, not surprising that the examples are multiplied in which water and other ingesta known to be infected have been swallowed, intentionally or accidentally, by healthy persons, without harm. If, however, this living infectious principle, the comma-bacillus of Koch, escape beyond the lower end of the stomach and pass into the small intestine, the contents of which have an alkaline reaction, multiplication with enormous rapidity therein, elaboration in considerable quantity of the poisonous ptomaïne, and the establishment of the disease which we recognize as Asiatic cholera become possible.

PROPHYLAXIS.

The considerations already advanced suggest prophylactic measures which experiment and experience have proven to be trustworthy. If the stomach be properly guarded against the introduction of the living infecting principle, the individual will be necessarily protected against the danger of an attack.

Protective measures may be considered from two standpoints: A, with regard to the person suffering from an attack of the disease; B, with regard to the healthy individual exposed to infection.

A. *With regard to the person suffering from an attack of the disease.* The evacuations from the stomach and the bowels should be immediately disinfected; if this is thoroughly accomplished, it is impossible for the infection to spread beyond the individual. The dejecta and the vomited matter should be passed into a vessel containing a quart or more of a strong solution of carbolic acid—one part to twenty of water—or of chloride of lime ten per cent. strong; and immediately after the evacuation a sufficient amount of the disinfectant should be added to make the whole quantity equal to the bulk of the evacuated material; the whole should then be gently stirred, and afterward allowed to stand at least twenty minutes, when it should be removed and emptied into a pit containing unslaked lime, and be immediately covered by a quantity of the same material.

The clothing of the patient, as well as the soiled bed-linen, immediately after removal, should be disinfected by thoroughly soaking for an hour or more in a large quantity (more than sufficient to cover them) of a strong solution of carbolic acid or chloride of lime one part to twenty; or they should be immediately subjected to the prolonged action of boiling water or steam. The anus, hands, and mouth of the patient should also, immediately after an evacuation, be washed with a disinfectant—in this case, however, weaker than has been indicated, say one part to two thousand of mercuric chloride and water, for the anus and hands, and for the mouth water slightly acidulated with sulphuric acid. The hands of the attendants, also, should be washed with the same weak solution of mercuric chloride after handling the patient. Under no circumstances should the attendant, or anyone else, eat in the same room with the sick; and, as an invariable rule, which should be scrupulously observed, no person who has been in direct contact with the sick or with any of his personal effects should eat without first thoroughly cleansing and disinfecting the hands.

B. *With regard to healthy persons exposed to the infectious principle of the disease:* Remembering what has already been remarked concerning an increased susceptibility to infection by reason of disturbance of the digestive apparatus, it is strenuously insisted upon that all causes, of whatever nature, of disturbance of the functions of the stomach and intestines, should be studiously avoided: such as intemperance of all kinds, either in drinking or in eating; all irregularities of personal habits, either as to time of meals, occupation, exercise, or hours

of sleep; all emotional excitement should be removed; in short, every circumstance which experience has shown may exercise a disturbing influence upon these important functions should be carefully guarded against; the use of articles of food which are liable to occasion indigestion, or to cause an unusual or unhealthy activity of the digestive apparatus, should be interdicted; children should be carefully prevented from indulging in exhausting sport or exercise, and should be carefully shielded against intemperate weather; it is all-important that the functions of the skin should be kept regular and active by a sufficient amount of seasonable clothing by day and by night; particular care should be taken that revulsions of blood, produced by chills, from the cutaneous surface to the internal organs, especially the abdominal, may not occur, and in this connection it is strongly recommended that the abdomen be enveloped at night in a broad band of flannel, in order that during the restlessness in sleep the skin of the abdomen may not be exposed to the direct action of the air; cold baths should be avoided; the surface of the body should be washed at not too frequent intervals, by sponging with tepid water, and afterward dried thoroughly by vigorous rubbing with a rough towel; meanwhile, the body should be protected from draughts. Irregularity and intemperance in eating and drinking have already been alluded to. It is important that the imbibition of large quantities of water or other fluids at intervals between meals be avoided, for, if there were no other reason, it is a well-known physiologic fact that in the intervals of digestion the reaction of the gastric juice is neutral and sometimes even slightly alkaline. If contaminated water or milk should be swallowed in large quantity during this interval, it is clear that the probability of the living infecting agent passing through the pylorus into the small intestine is greatly increased, and the possibility of an attack much enhanced. In a house in which a cholera-patient is suffering, the children and all others not in attendance upon the sick should be kept out of the sick-room. But if, as often occurs among the class of people who are mostly the sufferers from cholera—the poor and the squalid—there be only one common room for the use of the family, no one should on any account be permitted to occupy the same bed as the sick, and during the day, as also during the night, all should avoid as much as possible contact with the sick-bed.

Attention to the preparation of food is a matter of extreme importance to all persons exposed to the infection of cholera, and especially to children. It goes without saying, that the materials consumed should be perfectly fresh and sound in every respect, and that the water and milk employed should be absolutely free from the living infecting principle, as well as pure and healthy. As a guaranty against the possibility of infection by means of water or milk, both should be thoroughly boiled before use, and, as it is possible for the cholera-microbe to multiply rapidly both in water and in milk, the boiling should have been *very recent*. Coffee and tea should have been *recently* made and be *served hot*. All food should have been *thoroughly* and *recently* cooked. No raw food of any description, except possibly a moderate quantity of perfectly fresh, ripe, and absolutely clean fruits should be eaten. *Salads* and other such articles should be *interdicted*. Bread, as well as butter, should be carefully protected against the possibility of contamination. The culinary utensils and tableware should be *scrupulously cleaned with boiling water*.

The hygienic condition of the dwelling and its surroundings should be made as perfect as possible. All decaying animal or vegetable matter should be removed. The house-drains should be free and clean, and flushed with a sufficient amount of water at intervals, preceded by the emptying therein of a liberal quantity of strong solution of copperas in water, or of a 5 per cent. solution of carbolic acid, or equal strength of chloride of lime. The cesspits and the privies should be kept clean and free from odor by unslaked lime, large quantities of copperas, or other similar inexpensive materials. The supply for *drinking-water should be scrupulously guarded from possible contamination of any kind.*

Among the precautions to be enforced against a threatened attack of Asiatic cholera in anyone, but especially in the young, one of exceeding importance is watchfulness over the condition of the alimentary canal. In a large number, perhaps in the majority, of instances, an attack of cholera is preceded for some hours or days by derangements of the digestive apparatus, such as distress or a sense of fulness or heaviness in the stomach, of gastralgia or nausea, or of occasional vomiting; or the disorders may be limited to the intestines only, and be manifested by vague general abdominal uneasiness, or slight fleeting pains, or active peristaltic movements which can be seen or felt through the abdominal walls; and all or any of these may be associated or end with diarrhea, and sometimes with a tendency to disproportionate prostration; or, the disorders of the stomach and intestines may be combined; or, the attack may be fulminant without such warnings.

If these disturbances of the alimentary tract are promptly discovered and remedied, many an attack of cholera will be thereby avoided. In such cases, absolute rest in bed, and, if possible, also total abstinence for a day or two from food, should be enjoined; if there be reason to infer the presence in the stomach of undigested food, a single emetic dose of ipecac should be administered; or if there

be visible peristaltic movements of the intestines, or diarrhea, these should be controlled respectively by small doses of opium in a convenient form, and of such drugs as salol, naphthalin, or analogous compounds.

What has thus far been said applies especially to individuals; but, unfortunately, in this disease public interests and relations must also be regarded, and from this standpoint, *so long as there are in the locality only a few scattered cases of the disease*, the utmost efforts should be made to prevent the establishment of an epidemic.

It is obvious that the evacuations of the intestinal canal of the attacked should, without loss of time, be carefully disinfected. But by no means all suffering from an attack of cholera infectiosa are, especially in the earlier stages of the disease, so ill that they cannot be out of bed, and even out of doors engaged in their ordinary vocations. Yet experience has abundantly proved that those suffering "a walking attack" carry in their intestinal canal the infectious agent of cholera, and are capable, under favoring circumstances, of establishing a center of infection wherever in their movements they may chance to void those intestinal contents. Hence the necessity of temporarily restricting the liberty of all inmates of the infected dwelling and of all persons in close communication with it, whether at the time of infection they are evidently suffering or not. All such persons should be isolated and kept under strict surveillance until the extreme limit of the period of incubation (say, five or seven days) has fully elapsed, *counting from the commencement of the surveillance*. If during these five days no sign of even a slight or "walking attack" has made its appearance, and finally if a culture-test, as already described, of the feces has indicated the absence of the comma-bacilli of Koch, the individual temporarily restrained of his liberty both for his own benefit and for that of the public, may without danger be again restored to the full enjoyment thereof.

THE ABILITY OF THE STATE TO PREVENT AN EPIDEMIC OF CHOLERA.[1]

BY BENJAMIN LEE, M.D.,
SECRETARY OF THE STATE BOARD OF HEALTH OF PENNSYLVANIA.

THERE are two ways of preventing an epidemic of Asiatic cholera: the one, by a perfect system of quarantine to prevent a single germ of the disease from entering the country to be protected; the other, by the enforcement of enlightened and strict sanitary regulations to remove all conditions favorable for the propagation of the germ should it enter. This latter is the English way.

[1] Read before the Philadelphia County Medical Society, September 14, 1892.

The system of seacoast quarantine in Great Britain, as has long been known to American sanitarians, is defective in the extreme. Recent disclosures have developed the fact that there is really no power in the Government to enforce quarantine. The great British doctrine of free trade seems to have been pushed to its utmost limit to include disease as well as other commodities. This system may prove successful. It may be possible to introduce the germs into a community and to have everything in such an admirable condition of cleanliness and such strict enforcement of local precautions that the germs will quickly die. This seems to have taken place in England during the past fortnight. But to accomplish this result there must be a complete and thorough sanitary organization of the country, so that no foot of ground escapes frequent sanitary inspection and no accumulations of filth are allowed to remain upon its surface or beneath the surface for an hour.

In England, every householder is liable at any moment to a visit from an agent of the Board of Health. If this agent finds the least infraction of the rules of the Board, so much as a piece of bone lying on the ground which should be in the garbage receptacle, he whips out his tablet and makes a note of the fact and says, "You are fined so many shillings." The fine is paid on the spot. Such is the sanitary organization of England, with the Local Government Board at its head, controlling the whole system. Such, unfortunately, is not the sanitary organization of all of the States of this Union. Hence it would be folly for us not to make every effort to render the first plan successful. Evidently neither should be relied on alone. The one should supplement the other.

The subject assigned to me by your Directors may be considered from two points of view: the ideal and the actual—the ideal based upon conditions which are entirely practicable and possible; the actual based upon conditions now existing in this State.

The ideal conditions for defence against cholera are:

First. Thorough sanitary organization of the State, no portion of its territory to be without its legally qualified health-officer, having a district not too large for faithful and frequent personal inspection; such officer to be well paid for his services, and to be subordinate to a county or district health-officer, also properly remunerated, and all to be controlled by the central health-authority of the State.

Second. A sanitary code at least as perfect and strict as that of a large city—Philadelphia, for example—for the entire State.

Third. A national quarantine service, with ample

powers and means, having a station at the mouth of every large bay or river on which are ports of entry, as remote as possible from centers of population, with occasional refuges, remote from channels of commerce, to which ships and effects demanding an unusual amount of disinfection can be remanded if necessary.

On this question of the importance of a uniform and comprehensive system of coast-defence under national *régime* I feel very strongly.

I may be pardoned for alluding to a paper which I read before the National Conference of State Boards of Health in 1888, in which I answered affirmatively the question, "Should the National Government Assume Control of Quarantine at All Ports of Entry?," to a paper which I read before the Section on State Medicine of the American Medical Association, in the same year, entitled, "Should Not the National Government Defend Our Ports against the National Enemy, Contagious Disease?" and to a "Report of Inspections of the Quarantine Stations of the Middle Atlantic Coast," made to the National Conference of State Boards of Health, at the close of which I suggested the following evils as incident to the disjointed system of State and municipal quarantines:

"*First.* Want of uniformity in quarantine regulations.

"*Second.* Conflict of authority, owing to the methods of appointing officials.

"*Third.* The entire lack of appreciation on the part of local Legislatures, whether State or municipal, of the importance of the expenditure of considerable amounts of money in order to render quarantines at once efficient and inoppressive.

"*Fourth.* The tendency on the part of local civic authorities to limit their responsibility to the protection of their own city."

The fourth condition which I would propose is: A municipal quarantine service for all large cities, by which vessels can be subjected to a second scrutiny whenever circumstances render it necessary.

I have no hesitation in saying that, with the foregoing conditions, in view of our present accurate knowledge of the habits and habitat of the cholera-bacillus and its mode of propagation, for which thanks are due, among others, to our distinguished fellow-member, Dr. Shakespeare, the ability of the State to prevent an epidemic of cholera is absolute.

Now let us come to actual conditions, which are what more nearly concern us at the present moment: What as to the ability of this particular State of Pennsylvania to exclude the disease or to prevent its becoming epidemic?

I placed as first among the essentials of immunity, sanitary organization of the State and a State sanitary code, because I believe them to be the most important. In these grand fundamental requirements of an enlightened civilization I regret to be compelled to say that Pennsylvania is absolutely deficient. Notwithstanding the repeated importunities of the Board of Health, the Legislature persistently declines to legalize boards of health or health-authorities of any kind outside of large cities. The only appeal that our people living in towns, villages, and rural districts have when their neighborhood is invaded by epidemic disease, or when suffering from some intolerable nuisance that endangers the public health, is to the State Board of Health. It is not difficult to understand how utterly impossible it is for a single Board, with one paid officer, and four thousand dollars a year to work with, to give any adequate attention to the complaints of three million people scattered over an area of forty-five thousand square miles.

The constant cry that comes up to the ears of the Board is: "Our village is in a most filthy condition; our children are dying of diphtheria; typhoid fever is rife; and we are entirely without health-authorities of any kind. Will you not come and help us?"

In its efforts to render aid in such cases the Board finds itself at once hampered by the fact that the State is almost entirely without sanitary statutes. In order to enforce its orders it must have recourse to the slow process of the law and trial by jury. In other words, the State of Pennsylvania is without a sanitary code.

These being the conditions, the ability of this State to prevent cholera from becoming epidemic, should its germs find their way into its densely populated and filthy mining towns, is more than doubtful. Once let it become epidemic along the course of the Schuylkill River, and Philadelphia may repeat the experience of Hamburg.

In the absence, then, of any proper provision for sanitary officers, the Governor of this State was eminently justified in urging the people to unite in voluntary organizations, and appoint sanitary committees for the purpose of putting their respective towns in a state of sanitary defence. This they are doing to an encouraging extent, but, of course, they labor under a great disadvantage from lack both of authority and of experience.

Regarding our third condition, the outlook is extremely encouraging. The United States Quarantine Station at the mouth of Delaware Bay is in many respects well equipped. Its deficiencies are being rapidly made good. Its officers are efficient and experienced. It is remote from any large center of population, and of sufficient extent to accommodate a large number of suspects. I have strong faith that the enemy will not pass this outer

line of coast-defence. Should it do so, it will be met by the united forces of State and city at the Lazaretto, and, while the unfortunate contiguity of that station to this city and to the city of Chester and a populous neighborhood must be admitted, yet the energy and decision with which the Board of Health of this city and the State Quarantine authorities connected with this port are meeting the emergency, and supplementing the altogether inadequate and antiquated plant at the Lazaretto with modern appliances and increased accommodations, afford reasonable ground for hope that the onward march of the disease will be finally checked at that point.

Our fourth condition, therefore, while by no means all that could be desired, still exists in such a state of preparation that we may place considerable reliance upon it.

As I understand the situation, then, our danger here in this city lies not so much in an open invasion by way of the Delaware River as in a covert movement by flank and rear, through other ports, or possibly through merchandise introduced at this port, aided by the coöperation of those powerful allies, filth and absence of sanitary law and organization.

To guard as far as possible against this indirect introduction of the disease through other ports, the State Board of Health has promulgated the following order:

"*To Transportation Companies:*

"In accordance with Regulation III of this Board, in regard to the sanitary supervision of travel and traffic, which reads as follows:

"'Upon satisfactory information of the approach to or transit through the Commonwealth of Pennsylvania of infected persons or goods, it shall be the duty of the Secretary, as executive officer of the Board, to cause the same to be stopped at the State line, or, if found within the limits of the State, to cause such persons or goods to be removed from cars, stages, vessels, boats, or other conveyances, and securely isolated and disinfected; and he may, if in his judgment the emergency is such as to demand it, call a meeting of the Committee on Travel and Traffic, to which his action shall be submitted, with his reasons therefor, in writing. But, in cases coming under the jurisdiction of national or municipal quarantine authorities, he shall coöperate with said authorities in all such action'

"Notice is hereby given to the officers of all transportation companies, whether by land or by water, that any transportation company shall be declared contraband of quarantine which shall introduce, land, or transport within the borders of this Commonwealth of Pennsylvania any person suffering from Asiatic cholera or cholerine (so-called), or any person who shall develop said disease within four full days after having been so introduced, transported, or landed within the borders of said Commonwealth by such company.

"If a railroad company be thus declared contraband of quarantine its trains shall be stopped at the State line, and held until inspected by an inspector of this Board and declared by him free from the danger of conveying the contagion of Asiatic cholera into this Commonwealth.

"If a steamboat, canal, or other navigation company, its boats shall not be allowed to enter any dock, tie up at any wharf, or by any means land passengers, baggage, or merchandise until it has undergone like inspection, and been declared free from danger of introducing the said contagion into the Commonwealth of Pennsylvania.

"By order of the Board,

"BENJAMIN LEE, M.D.,
"Secretary and Executive Officer."

As a further matter of precaution, the Board has issued the following instructions:

"*To the Officers of Railroad and Steamboat Companies in Pennsylvania:*

"The principal railroad companies operating in this State have adopted admirable regulations for the sanitary care of their cars and premises under ordinary conditions. The State Board of Health has already taken occasion to commend these, as well as the readiness of these companies to coöperate with it in efforts to protect the public health. In view, however, of the threatened invasion of Asiatic cholera, it is important to enforce these regulations with unusual strictness, and to take certain additional precautions.

"The Board therefore orders:

"*First.* That all water-closets and urinals in cars be provided with proper water-tight receptacles for retaining deposits, instead of allowing them to fall on the track, and thus endanger water-supplies; said receptacles to contain disinfectants, and to be renewed at certain intervals in such places and in such manner as may be determined upon for the most perfect protection against infection. The adoption of the precaution should be begun with second-class and immigrant cars, and extended as rapidly as possible to first-class cars.

"*Second.* Should the discharges of the sick fall upon seats, floors, or platforms of cars or stations, they should be first disinfected, and then removed in closed buckets, and the soiled places then disinfected and thoroughly cleaned.

"*Third.* All cars coming from infected places shall be disinfected before sweeping, and the sweepings disinfected and burned.

"*Fourth.* All water-closets and urinals in steamboats and canal boats shall be provided with proper water-tight receptacles for retaining deposits instead of allowing them to fall into the water, which is in most instances the supply of drinking-water for some center of population. Such receptacles shall always contain disinfectants, and shall be emptied at the end of each trip in such manner and in such place as may be designated by the local authorities.

"*Fifth.* All accumulations of filthy clothing and rags shall be at once disinfected and burned.

"*Sixth.* Should cholera become epidemic, the drinking-water furnished for the use of passengers should be boiled, and, so far as possible, should not be obtained from places in which the disease exists.

"By order of the Board,

"BENJAMIN LEE, M.D.,
"Secretary and Executive Officer."

The campaign throughout the State and on the borders being thus outlined, we come to perhaps the most important question of all, where the ability of the State is concerned, viz., the sinews of war. Much work of the utmost importance should be done under the superintendence of the State Board of Health. But whence is the money to come to pay?

The laws make provision for the expenditure of the State's funds with the utmost lavishness for the protection of property; but, when nothing more valuable than human life is concerned, there is no authority for the disbursement of a single penny from the treasury beyond the meager appropriation to the State Board of Health already mentioned.

THE MORBID ANATOMY AND DIAGNOSIS OF CHOLERA.[1]

BY JAMES TYSON, M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

THE picture of the essential morbid anatomy of cholera is neither complex nor varied, but repeats itself with tolerable simplicity and uniformity. A comparison with the more condensed accounts to which the proceedings this evening are comparable leads me to believe that its essentials do not include much more than is covered by the description of an autopsy made by myself at the Philadelphia Hospital in 1866 or 1867.

The patient was a woman, aged twenty-nine, who died after an illness of twenty-four hours.

The examination was made one hour after death, and the central portions of the body were still warm.

Abdomen. The *stomach* was filled with turbid liquid, grayish-white in color, resembling rice-water. In this the microscope discovered numerous columnar epithelial cells, isolated and aggregated, forming flakes; also disintegrating muscular fasciculi, doubtless from beef-essence taken during life. The mucous membrane of the stomach appeared much congested, and the distribution of the larger vessels could be readily traced in consequence of their being filled with thick blood. My notes read that the papillated appearance ascribed to enlargement of the solitary follicles was present, though less distinct than that described in published reports of post-mortem appearances.

The epithelium was detached in some places, in others intact.

The *liver* was natural in size, but congested and darker-hued than in health. Its cells, as determined by microscopic examination, were normal.

The *kidneys* were normal in size, but appeared dark-hued and congested. The tubules and lining cells were normal.

Thorax. Both *lungs* were firmly attached by old adhesions; the lower lobe of each was hypostatically congested, but otherwise they were normal.

The *heart* was normal in size, but its walls were somewhat flaccid. There was a small, currant-jelly clot in the right ventricle, and the remainder of the cavity, as well as the left ventricle, was filled with dark, liquid blood.

The mucous membrane of the small intestine was also much congested; the bowel contained no fluid, but was distended with gas. On its surface lay numerous patches or flakes of greenish color, which on microscopic examination proved to be epithelium. The papillated appearance produced by enlargement of the lymphadenoid follicles was everywhere present.

Microscopic examination showed the villi largely denuded of epithelium, but not completely, and in places a considerable surface was intact.

Such is the description of the appearances found at an autopsy twenty-five years ago, one of several made at that time, and, with some changes, it may be regarded as a type of those cases. In most cases the intestines also contained the rice-water liquid; in some this was absent from the stomach. The appearances are not materially different from the macroscopic morbid features of the more recently described cases. The additions that modern studies have made are histologic rather than macroscopic, but they are of infinite importance. In addition to a cellular infiltration, more or less dense, of the mucosa, the submucosa, and even the serous coat, there is found the *comma-bacillus* in immense numbers in the contents of the intestine, more rarely in the stomach, and in protracted cases in the intestinal wall, in its follicles, and even deeper tissues.

The congestions, referred to as present in the lungs and mucous membrane of the stomach and intestines in my case, would seem to indicate that some reaction had been established, as these organs are commonly anemic when death takes place during collapse. The same is true of the liver and kidneys, which are more frequently described as pale and flaccid. The heart more frequently has its right cavities filled with thick, dark blood, while the left side is empty. In many instances, the lungs also present an appearance more or less characteristic, being shrunken and small and lying back in the thorax, as though collapsed. Under these circumstances they are like the other tissues, empty of blood, except in their dependent portions, which are the seat of a hypostasis such as described in my own case. They have been compared by Parkes to fetal lungs, and by Sutton the two organs were found to weigh but twenty ounces, as compared with forty-five ounces when death occurred after reaction had been established—that is, after the blood had again occupied the pulmonary artery and its branches. In some cases this collapse is but partial, as when interfered with by adhesions, as also was found to be the case in my own patient.

Such appearances could, of course, occur in death from hemorrhage, and, after all, the only essential condition is the presence of rice-water fluid in the stomach or intestine, or in both, containing the "comma" bacillus and desquamated epithelium. The last, to which the earlier descriptions attached

[1] Remarks made at the meeting of the Philadelphia County Medical Society, September 14, 1892.

great importance, is now generally regarded as post-mortem in origin. The flakes thus produced probably represent also the patches of lymph described by the older authors.

If death take place during the stage of imperfect reaction, the mucous membrane is much more frequently found congested and of a dark-red color, from the hyperemia and extravasation of blood. At such time, too, the solitary glands are conspicuous, as also are Peyer's patches, and the same denudation of epithelium from the villi and elsewhere is present. The only signs that suggest an inflammatory process are the slight cellular infiltration of the intestinal walls and the enlargement of the solitary follicles.

In the matter of *diagnosis* it is well known that, so far as symptoms are concerned, cases of cholera-morbus, cholera nostras, or sporadic cholera, as we may prefer to name it, have occurred with symptoms absolutely identical with those of true cholera, including the fatal termination. It is not worth while, therefore, to attempt to contrast the clinical features of true cholera with those of cholera morbus, with which alone it is likely to be confounded. By bacteriologic investigation only, including also cultivation on artificial media, can a given case be identified with absolute certainty. Dr. Abbott informs me, however, that fifty-two hours is the minimum time required to complete such a bacteriologic diagnosis. Further, such investigations can only be made by those who are expert, and provided with proper facilities. Such expertness and facilities, moreover, are not found in the hands of general practitioners, and the bacteriologic investigation is therefore of limited application.

As to microscopic examination of the dejecta, which is more feasible for the practitioner, it may also be said that if the examination reveals a preponderance of curved bacilli, comma-shaped, and sometimes joined end to end so as to form figures somewhat resembling the letter S, and again appearing in longer threads, we may feel justified in considering the case one for careful study by bacteriologic methods. Although there are found in the alimentary tract other bacilli the morphology of which is much like that of the cholera-bacillus, they are not numerous.

How, then, shall we know a case of vomiting, serous diarrhea, severe colicky pains, followed by collapse, to be a case of cholera? In this country, where such a thing as endemic cholera is unknown, it goes without saying that any isolated case, even if fatal, cannot be one of true cholera, unless there be traceable some connection with an acknowledged focus of cholera elsewhere. Second, such communication must have taken place within the period of incubation required for the development of a case—say within six days. Of course, such communication need not be a personal one. It may be by clothing, merchandise, and probably even by letter.

These conditions being fulfilled, the patient suffering with the symptoms of cholera must, for the time being, be regarded as a case of the true disease, and isolated until the bacteriologic investigation can be made, but the rapid occurrence of similar cases increases the probability of its being true cholera, and finally establishes its certainty. Yet, local epidemics of cholera-morbus do sometimes take place, severe and grave in character, due to local causes, and favored by extreme and long-continued heat. Thus it is still a question whether the recent epidemic of cholerine that prevailed in Paris in May, June, and July of this year, was true cholera or cholera-morbus, and there seems much reason to believe it to have been the latter, notwithstanding the prevalence of true cholera.

There is one very important etiologic rather than clinical difference in the two diseases which is also of great diagnostic value, and that is this: that almost invariably cholera-morbus is traceable to a severe and irritating exciting cause, such as a meal of indigestible fruits or vegetables, or imperfectly cooked or decomposing fish or shell-fish; while cholera comes on without any such cause, or succeeds trifling derangements of digestion, which in other than cholera-seasons pass away without harmful results. As a rule, too, the symptoms of cholera-morbus are much less severe than those of true cholera, and the matters first vomited are the undigested matters that have acted as the exciting cause, succeeded by green, bilious matter. The discharges from the bowels are also at first more of a bilious character; and above all, the mortality is much less serious. Indeed, recovery is the rule. Yet, as already stated, these distinctions alone are not to be relied upon.

SUGGESTIONS AS TO THE PROPHYLAXIS AND TREATMENT OF CHOLERA.

BY D. D. STEWART, M.D.,
CLINICAL LECTURER ON MEDICINE, JEFFERSON MEDICAL COLLEGE.

THE important discovery of the illustrious Koch of the probable *contagium* of true cholera, thus endowing the disease with an individuality the most important characteristics of which could be readily ascertained, will doubtless lead eventually to a successful therapy based on antagonism of the products of the germ's activity, and perhaps finally to the practical extinction of the disease through a conferring of immunity by vaccination, and the adoption of comprehensive sanitation, aimed at eradicating the disease in its perennial endemic quarters.

As yet, however, little has been accomplished

practically by Koch's discovery in any direction other than that of hygienic prophylaxis. The specific leukomaïne of the spirillum has not been isolated nor has its antidote been ascertained. Little of practical importance has, indeed, yet been accomplished if we take no cognizance of the claims of Ferran, who, until Shakespeare's valuable *Report on Cholera in Europe and India* recently appeared, was generally viewed as the merest charlatan, and the active principle of whose inoculating material was said to consist rather of a substance resembling croton oil than a pure culture of cholera-bacilli. If Ferran's assumptions are reliable, it seems curious that no effort has been made outside of Spain to utilize so important a discovery as the conferring of more or less persistent immunity against cholera by inoculation. This is in all probability due to an unfortunate prejudice existing against Ferran, who apparently was more desirous of pecuniary reward as a result of his discovery than of lasting fame as a philanthropist, and who, therefore, surrounded his methods with sufficient secrecy to invite suspicion of chicanery.

Very recently the experiments of Brieger,[1] undertaken on the same lines as those of Ferran, indicate that the latter's claims as to the production of artificial immunity in animals and man to the toxic action of the cholera-germ were not extravagant, and that we are on the eve of their complete confirmation. Unfortunately, Brieger has not yet extended his experiments to man, though this will likely soon follow. However this may be, at present a protective vaccination is not available as a means of meeting a visitation of cholera, so that other less certain measures must be sought of securing individual immunity.

A knowledge of the peculiarities of the contagium of cholera permits us to adopt certain safeguards of more or less value, depending upon the thoroughness with which they can be carried out. It is now generally believed that infection occurs through no other channel than the mouth, and usually originates through the ingestion of contaminated water (or watered milk). But the greatest caution as to drinking only thoroughly and recently boiled water, even when one does not come in contact with cholera-patients, and has, therefore, no opportunity of soiling the hands with the dejecta, will not always protect from the disease, as there are many unforeseen channels during an epidemic through which the food or hands may become contaminated.

As the comma-spirillum is not spore-forming and readily perishes in acid media, the normal stomach acidity being sufficient to render it inert, it follows that though taken in some quantity with the food by an individual with a healthy digestive apparatus, infection is unlikely to occur.[1]

It is for this reason that attention to gastric digestion is doubly indicated during an epidemic of cholera, and that, in addition to the caution necessary in the selection of non-contaminated food and drink, care must be paid to the amount and quality, that, apart from the danger of originating stomach or bowel disturbance, the germ does not escape destruction in the stomach should it gain entrance with the food. For a similar reason, in addition to the usual precautions now universally advised and generally known, as to the use of only thoroughly boiled water for drinking and for culinary purposes, and the care necessary in the selection and preparation of edibles, I should strongly advocate in all persons suffering from any form of gastric derangement attended with subacidity, whether it be gastric catarrh or the so-called nervous or atonic dyspepsia, the administration of hydrochloric acid in full doses after meals.

It is surprising to one unaccustomed to the use of the stomach-tube to find how many have lowered acidity who, in seeking advice, do not particularly complain of gastric symptoms. Among all, save the most robust, with undoubted vigorous gastric digestion, and those whose symptoms indicate a heightening of the normal gastric acidity, the use of hydrochloric acid would be advisable. As it is best given in gastric catarrh, so it should be prescribed here, in doses of about a teaspoonful of the dilute acid to eight ounces of water, taken in two or more portions at intervals of from ten to fifteen minutes, the initial dose being delayed until a half-hour after a meal in which amylaceous food forms a part. The acid here serves a double purpose of germicide and digestant.

As a further prophylactic, where it is suspected that infection may occur, despite the adoption of the commonly advised precautions and the attention given to gastric digestion, as through fluids ingested on the empty stomach, it has occurred to me that an insoluble, harmless antiseptic, such as hydronaphthol, would be especially indicated. This drug particularly has suggested itself in this connection, as I have now used it largely for seven years with the very best results, in cases of intestinal disturbance of various kinds induced by fermentative processes. The chief ill-effects of cholera are probably due to the action of the spirillum or its leuko-

[1] Brieger (*Deutsche med. Woch.*, 1892, No. 31) has recently succeeded by inoculation in rendering guinea-pigs absolutely immune to virulent cultures of cholera-bacilli, a much smaller dose of which had a prompt lethal effect on non-prepared pigs. The method consists in the intra-peritoneal injection of comma-spirilla cultures prepared on watery extract of calves' thymus or in beef-bouillon.

[1] It is in this manner, as suggested by Koch, that Rochefontaine, in Paris, and Klein, in Bombay, escaped infection after swallowing—the one, pills of cholera-dejecta, the other, a liquid supposed to contain comma-bacilli.

maïne on the mucous membrane of the lower part of the ileum. Any agent tending to destroy or inhibit the development of the organism, that could be transported unchanged to this part of the bowel, there to exert its specific effect, would probably be of service both in preventing the development of the disease and in diminishing its virulence if it already existed.

Because of salol having a lethal action on comma-spirilla in the presence of pancreatic juice, which latter promotes its decomposition into salicylic acid and phenol, Loewenthal and others have urged its use both as a prophylactic and as a remedy for the developed disease. But since salol is promptly dissociated into its components by the action of the alkaline juices of the duodenum, and as the nascent salicylic and carbolic acids formed are quickly converted into soluble salts, it is unlikely that any portion of the drug will reach the lower segment of the ileum in quantity sufficient to exert a favorable effect, unless the alkalinity of the bowel is abnormally feeble, or doses are resorted to that are not compatible with safety.

Hydronaphthol is a comparatively insoluble substance, dissolving in the proportion of 1 : 100 of boiling water, which on cooling largely precipitates, leaving a solution about 1 : 1000. In cold water it is soluble to the extent of 1 : 2000. Its solubility in the bowel is unaffected by the action of the gastric or the intestinal secretions. Sufficient, however, enters into solution to exert a very powerful effect on putrefactive processes in these viscera. In doses of from three to five grains, three or four times a day, it readily checks a tendency to intestinal flatus, and though possessing no astringent property in itself, it will usually promptly jugulate a diarrhea, evidently through its antiseptic action. One of the most intractable cases of chronic dysentery I ever encountered, in which profuse hemorrhages from the bowel frequently occurred, as a result of intestinal ulceration, and which had resisted all ordinary treatment, including injections of silver nitrate solutions, was controlled with surprising readiness by the use of this medicament. Intestinal hemorrhage ceased within a few days after its first administration, and diarrhea soon after. So much confidence have I in this drug as an intestinal antiseptic, that I have used it for a number of years as the only medicament in nearly every case of enteric fever that I have treated, lately combining the Brand method with it. In no case in which it has been resorted to early in the course of the disease has the attack been a severe one, and few plunges have been necessary. My results having been so invariably good with hydronaphthol in intestinal affections of mycotic origin, I feel constrained to urge its trial as both a prophylactic against and a remedy in cholera. A suitable dose would be from five to ten grains three or four times daily. As it has a slightly retarding effect on gastric digestion, but none whatever on duodenal digestion, it may be prescribed in keratin-covered pills, the coating of which is soluble in the alkaline secretion of the duodenum.

Hydronaphthol should be especially of service in early choleraic diarrhea, to check which a preparation of opium is usually given. Though there is no doubt, from an abundant experience, that opium cannot ordinarily be resorted to too early in cases of diarrhea during the prevalence of cholera, it must be borne in mind that, though often successful in checking an intestinal flux, presumably choleraic, treatment by it is but symptomatic, for opium can neither destroy the comma-bacillus nor retard its development; indeed, the experiments of Koch with guinea-pigs indicate that this drug actually favors the latter. Opium apparently acts in early choleraic diarrhea by checking the bowel-irritiation originated by the spirillum, or its peculiar poison. Hydronapthol would presumably act synergistically with opium by its lethal effect on the germ, or at least by inhibiting its multiplication and the production of its leukomaïne.

NOTE.—My friend, Dr. A. A. Ghriskey, assistant in Hygiene in the University of Pennsylvania, has kindly undertaken some experiments for me as to the action of aqueous solutions of hydronaphthol, of various strengths, on pure cultures of the comma-spirillum, a full account of which will be published in a subsequent issue of THE MEDICAL NEWS, they not having been carried to a finality sufficient to permit of a report at this time. I may, however, now state that the indications are favorable as to the utility of the drug in the direction stated.

MEDICAL PROGRESS.

Artificial Immunity to Cholera.—G. KLEMPERER (*Berlin. klin. Wochenschr.*, No. 32, 1892, p. 789) has succeeded in conferring immunity to Asiatic cholera upon lower animals by treatment with modified cultures of comma-bacilli. Guinea-pigs bore without detriment intra-peritoneal injections of 1 c.cm. of cholera-bacilli that had been kept for three days at a temperature of 104.9°. If the injection was repeated after an interval of twenty-four hours and two more injections, each of 1.5 c.cm., were then given, also at intervals of twenty-four hours, the animals on the fifth day survived injections of an otherwise lethal dose (1 c.cm. of a twenty-four-hour culture). Animals treated in like manner with cultures that had been kept for two hours at a temperature of 158° also survived lethal injections. Other animals that received a single injection of 2.5 c.cm. of cultures that had been kept for two hours at a temperature of 158°, likewise withstood a lethal dose two days later; it was determined that immunity existed seventeen hours after the protective inoculation.

While intravenous injections of 1.5 c.cm. of ordinary bouillon-culture of cholera-bacilli proved lethal to rabbits, a larger quantity was necessary if the culture had been kept for two hours at a temperature of 158°. Immunity to cholera was conferred upon rabbits by intra-

venous injections, in quantities short of lethal, of cultures of comma-bacilli that had been kept for two hours at a temperature of 158°. The best results were obtained by injecting 3 c.cm. of such cultures four times, at intervals of two days. Immunity was found to exist three days after the last injection. Guinea-pigs were rendered immune to cholera by inoculation with the serum of protected rabbits. The protection was most certain if the inoculation was practised three hours before the injection. When the inoculation was practised later, death was retarded, but not prevented. Among the rabbits rendered immune to cholera was one already immune to pneumonia. With the serum of this animal it was possible to confer upon guinea-pigs protection from cholera and upon mice protection from pneumonia.

The view is expressed that, unlike what takes place in man, intoxication and not infection results when cultures of cholera-bacilli are introduced into the gastro-intestinal tract of guinea-pigs, and dependent in degree upon the number of organisms introduced. It was ascertained that the degree of immunity necessary to protect from the intoxication resulting from the introduction of cultures into the alimentary canal had to be greater than was necessary to protect from intra-peritoneal infection. This immunity was, however, attained by two injections of 2.5 c.cm., with an interval of twenty-four hours, of the culture kept for two hours at a temperature of 158°, as well as by the injection twice, night and morning, of 2 c.cm. of the blood-serum of an immune animal.

Guinea-pigs to which had been administered by the mouth cultures of cholera-bacilli in quantities short of lethal, subsequently withstood lethal quantities given in the same way. This result corresponds with the immunity observed in human beings after an attack of Asiatic cholera. Cultures through which a constant current of 20 milliampères was passed for twenty-four hours were capable of conferring immunity in a manner and degree comparable to that conferred by cultures kept at a temperature of 158° for two hours.

Successful Evacuation of a Cerebellar Abscess.—DEAN (*Lancet*, No. 3596, p. 250) has reported the case of a girl, fourteen years old, who for five years had a purulent discharge from the right ear. For three weeks there had been pain in the head, especially in the mastoid region, where the skin was boggy and dusky. Consciousness was perverted and there was marked bilateral optic neuritis. The right tympanic membrane had been destroyed, and the middle ear was filled with flabby granulation-tissue. The mastoid process was opened and about half a dram of pus evacuated. The bone was curetted and the cavity irrigated. The lateral sinus was found to be pervious. Improvement followed the operation, but some days afterward, symptoms of intracranial compression appeared: headache, drowsiness, diminished frequency and intermittence of the pulse, depressed temperature, vomiting, derangement of respiration, and dilatation of the pupils. After the head had been shaved and sterilized, a semicircular flap of skin, just above and behind the right ear, was made, and the periosteum reflected. The pin of a trephine was placed an inch behind and a half inch above the center of the external auditory meatus, and a disc of bone, three-quarters of an inch in diameter, was removed. The dura was incised and a small hydrocele-trocar was inserted six times in different directions in the temporo-sphenoidal lobe, but no pus escaped. A few drams of cerebro-spinal fluid escaped from the lateral ventricle. The lateral sinus was found to be pervious. It was now decided to explore the right lobe of the cerebellum. By means of forceps, sufficient bone was chipped away downward and backward for half an inch to expose the lateral sinus and the dura below it. The latter was incised and the trocar introduced. At the second insertion pus escaped. A large trocar was then inserted, and finally a pair of sinus-forceps. More than an ounce of pus escaped. A rubber drainage-tube was introduced and the dura mater carefully laid over the surface of the brain, but not stitched. The usual outer dressing was applied. After the operation the condition of the patient progressively improved and the optic neuritis subsided. A slight purulent discharge from the right ear persisted.

The Surgery of the Biliary Passages.—KÖRTE (*Samml. klin. Vorträge*, 1892, No. 40) has reported the interesting features of twenty-two cases in which operations were performed on the biliary passages. Twelve cases were operated on for gall-stones; eleven of these were in women, all of whom had borne children. Six cases presented dropsy of the gall-bladder, in five associated with gall-stones. In four cases there was empyema of the gall-bladder, three with stones. In three cases the ductus choledochus was occluded by stones. Three cases died: one of choledoch-occlusion, of asthenia; one of suppuration of the liver; one of empyema of the gall-bladder, with calculi and carcinoma of the liver; none in consequence of the operation. In some cases multiple operations were necessary, but in all, the functions of the biliary apparatus were conserved, and in none did a fistula remain. Cholecystotomy was performed at one sitting five times; in two sittings twice. Cholecystotomy is considered the best procedure for empyema of the gall-bladder, for disease of the bladder-wall, as well as for occlusion of the choledoch duct. In case of gall-stones, without disease of the walls of the gall-bladder, and if the common duct is patulous, opening the gall-bladder and evacuation of its contents, followed by suture, are preferable. Cholecystotomy is the most rational procedure in most cases of calculi in the gall-bladder. In four patients with empyema of the gall-bladder serious sequelæ developed; in each, the bacterium coli commune was found in the bladder. One case of hepatic abscess, with perityphlitic suppuration, was successfully operated on. In seven cases subphrenic abscess was found; six of the patients recovered. In three cases hydatid cysts of the liver were opened. Of two cases of gunshot injury of the liver one recovered after laparotomy and tamponade; the other died from injury of the colon and peritonitis.—*Fortschritte der Medicin, 1892, No. 12, p. 470.*

The Diagnosis of Cholera.—LASER (*Deutsche medicin. Wochenschr.*, No. 32, p. 793) recommends the following diagnostic procedure for the recognition of the stools of a patient suspected to be suffering from an attack of cholera. A number of tubes of peptone-bouillon or peptone-gelatin are inoculated with the stools of the sus-

pected case, and a like number of tubes are inoculated with the stools of a presumably healthy person. Placed in the thermostat, in the course of twenty-four hours the tubes inoculated with the cholera-stool present a characteristic odor absent from the others. Care must be taken not to use too much fecal matter, as the odor of this may obscure the odor developed. If also a film has formed, and if in the course of forty-eight hours a reddish color can be produced by the addition of sulphuric acid, the diagnosis is absolute.

A Traumatic Neurosis.—COESTER (*Berliner klin. Woch.*, No. 31, 1892, p. 776) has reported the case of a lad, seventeen years old, in which, following a contusion of the ring-finger of the right hand, anesthesia of the right upper extremity, and of the right side of the head, face, and trunk to the level of the seventh rib, appeared. Tactile sensibility, thermic sensibility, and the sensibility to pain were abolished. The muscle-sense was preserved and there was no loss of power or wasting. The condition disappeared after six weeks of application of strong currents by means of the faradic brush.

The Differentiation of Hysteria and Epilepsy.—From a study of the urine in cases of hysteria and epilepsy, respectively, BOSC (*Compt.-rend. hebdom. des Séances de la Soc. de Biol.*, No. 28, p. 723) has determined that the chemical constitution and the toxicity of the twenty-four hours' urine are below the normal in cases of hysteria, and above the normal in cases of epilepsy. The urine passed immediately after an epileptic attack, in contrast with that passed after an hysterical attack, presents a diminution in the alkaline phosphates and an increase in the earthy phosphates.

Paradoxical Patellar Reflex.—EICHHORST (*Centrabl. f. klin. Med.*, No. 31, 1892, p. 641) has reported a case of acute anterior poliomyelitis in process of recovery, in which a tap upon the patellar tendon was not followed by contraction of the quadriceps femoris, but by contraction of the tibialis anticus, extensor hallucis longus, and extensor digitorum communis longus, at a time when voluntary power was beginning to return in the previously paralyzed but now responding muscles. The contraction was active, but slow, protracted, and vermicular.

Conservative Treatment of Articular Tuberculosis.—BIER (*Beiläge zum Centralbl. f. Chirurgie*, 1892, No. 32, p. 57) has treated more than twenty cases of articular tuberculosis, by means of continuous passive hyperemia, with speedy and marked improvement. The idea was suggested by the pathologic experience that hyperemic lungs are rarely, if ever, tuberculous. The desired end is attained by wrapping the joint well to a point just below the seat of disease, while above a rubber tube, protected by a soft bandage, is wound around the part.

Retro-pharyngeal Abscess After Influenza.—FISCHER (*Wiener medicin. Presse*, No. 30, p. 1204) has reported the cases of two infants, eleven and six months old, respectively, in each of which, following an attack of what was considered to be influenza, a retro-pharyngeal abscess developed, recovery following incision and evacuation. In neither case could disease of the vertebræ be detected.

THERAPEUTIC NOTES.

The Ice-cradle.—SOLTAU FENWICK (*Berliner klin. Wochenschr.*, No. 31, 1892, p. 767) describes a device that has been employed at the London Fever Hospital for ten years in the treatment of cases of typhoid fever, and, more recently, of cases of pneumonia attended with hyperpyrexia. An ice-cradle is made by suspending over the patient, in bed, by means of iron frames, a number of zinc buckets, kept half-filled with ice and inclosed in a light covering. The patient is covered with a muslin sheet, and provision is made for the circulation of the air in the cradle. The temperature of the patient is to be taken at least every four hours, and if it falls to 100° the apparatus is to be removed. If a sense of chilliness appears, hot bottles are to be applied to the feet.

For Oxyuris Vermicularis.—Enemata containing naphthalin are recommended for the expulsion of oxyures vermiculares. For a child:

℞.—Naphthalin . . . . gr. xv–xx.
Olei olivæ . . . . ʒx–ʒij.—M.
S.—As an enema.

For an adult:

℞.—Naphthalin . . . . ʒj–ʒjss.
Olei olivæ . . . . ʒij–ʒiij.—M.
S.—As an enema.

MINERBI.

Creasote by Enema.—In the treatment of pulmonary tuberculosis GRASSET (*Nouv. Montpel. Méd.*, No. 25, p. 500) administers creasote by the bowel, morning and evening, preceded by a simple enema. An emulsion is made as follows:

℞.—Tinct. opii . . . . . ♏jss.
Creasoti . . . . . ♏xv.
Olei olivæ . . . . . ʒijss.
Vitell. ovi . . . . . No. j.—M.

—*Gaz. Méd. de Paris*, No. 31, p. 371.

Hot Rectal Injections have been effectively employed for the relief of painful affections of the abdominal and pelvic viscera, such as renal colic, ovarian neuralgia, pelvic peritonitis, and dysmenorrhea. The water used must have a temperature of from 105° to 112°; a pint is at first carefully injected; after this (mixed with fecal matter) has been expelled, another pint is injected; a third injection is practised, and the fluid is usually retained.—FORER, in *Correspondenzblatt für Schweizer Aerzte*.

Salol for Cholera.—Based upon laboratory and animal experimentation, LOEWENTHAL (*Deutsche medicin. Wochenschr.*, 1892, No. 32, p. 738) has recommended salol in the treatment of cholera. Thirty grains should be given as the initial dose, followed hourly or half-hourly by doses of from seven and a half to fifteen grains. Gonzalez is quoted as having treated fifty-three cases of cholera in the manner outlined, with but three deaths.

REVISION OF THE CODE OF ETHICS OF THE AMERICAN MEDICAL ASSOCIATION.

WE take for granted the acquiescence of the overwhelming majority of our readers in the necessity for a Code of Ethics; for the reasons given in our editorial on the subject in THE NEWS of July 16th, and for those additionally advanced in the admirable letter of DR. COWAN, in THE NEWS of August 2d. The further question then arises: Is it wise to revise the present Code of the American Medical Association? We think the general sense of the profession would answer that while the Code, as it now stands, is an excellent guide for professional conduct, it is wise to subject it to revision for two reasons: (1) It contains much that is unnecessary and useless; and (2) a respectable number of members of the profession demands its revision and is dissatisfied with certain of its provisions. This dissatisfaction has expressed itself, in the State of New York especially, to such an extent that one of the most important sections of the Code—one, indeed, which has done more than any other to maintain the dignity of the profession—has been formally repudiated. The antagonisms produced by this act of repudiation on the part of the Medical Society of the State of New York have led to bitter dissensions, and created for a time a serious division in the profession. This division, however, is now practically healed, as far as the individual relations of members of the profession in New York are concerned; but the fact that many of those who, through the State Society, have repudiated the Code are permanent members of the American Medical Association puts the Association in a false and illogical position if their membership be recognized, or excludes certain able, eminent and honest co-workers if the laws of the Association be rigidly enforced.

One familiar with the Code contest in New York nine years ago, in looking back, must recognize the fact that this contest led to action that the majority of the partisans of the two sides would now willingly modify. The supporters of the Code would now be willing to see it stripped of useless provisions and redundant language, to say the least. The advocates of the "new code," or certainly the majority of its adherents, would now hardly support a provision which permits unrestricted consultation with homeopathists, eclectics, physio-medicals, advertisers *et id genus omne*. Indeed, most of the so-called "new code" members of the profession in New York now decline to consult with irregular practitioners, and make no exception even in favor of homeopathists.

It is time for the adherents of scientific medicine to come together and stand on common ground. It is now worse than useless to question the motives of those who either rebelled against or defended the Code, except in so far as an inquiry into motives may promote harmony and tend to restore mutual confidence. The American Medical Association should now endeavor to settle the ethical question permanently, and devote itself hereafter to scientific work. The Committee appointed to revise the Code should try to frame a document which will be cheerfully adopted by physicians generally, both individually and through the action of medical societies, leaving agitators and belligerents in the background. We believe that the great majority of those who have repudiated the Code have no desire to degrade the profession to the level of those classed as irregular practitioners, or to meet such practitioners on terms of professional equality; but rather that they honestly believe in the right to render their services to all, whether the patient be at the moment under the care of a physician or of an irregular practitioner. We believe, also, that the defenders of the Code resisted its modification on the highest moral and

professional grounds. If, then, it be conceded (1) that a Code is necessary and (2) that revision of the present Code is wise, the further question arises: In what respects is revision necessary?

All must admit that the phraseology of the existing Code can be much improved in the direction of conciseness. What is needed is a short and clear-cut set of rules for the guidance and direction of the profession, which may be referred to to decide delicate questions in regard to the relations of physicians to each other and to the public, and which, if adhered to, will provide against indiscretions into which members of the profession may thoughtlessly fall. A code of ethics is not for the public and has nothing to do with the "obligations of patients to their physicians" or the "obligations of the public to physicians." It has nothing to do with acts on the part of physicians that render them amenable to penal law. An ideal code is one that will sharply draw the line between the physicians, properly so-called, and irregular practitioners, will secure fair and honorable treatment of younger practitioners by their elders, and will indicate to the young physician, struggling for existence and professional success, both his rights and his obligations.

The code need not, and should not, include general exhortations and maxims that go without saying. In the existing Code there is much of this which well deserves the criticism that it has received. We should strike out such matter as the following: The "duties of physicians to their patients," which refer to promptly obeying professional calls, treating patients with tenderness, firmness, etc., unnecessarily frequent visits, form of prognosis to patients and friends, abandonment of hopeless cases, the desirability of promoting consultations, general directions for the "support of professional character," pecuniary acknowledgments, and all matter that is indefinite and general. It seems unnecessary, also, to say anything about the services of physicians to each other. This is regulated by custom and circumstances. Article III of the Code, "Of the duties of physicians as respects vicarious offices," refers to a question also regulated by custom and circumstances, and often a matter of special arrangement, except when a physician is called in cases of emergency. These eliminations would leave the Code with all of its useful provisions and reduce its length more than one half.

The Code should clearly and distinctly define the attitude of the profession and provide certain rules for professional conduct. We throw out as tentative suggestions what seem to us the most important points, and invite full and free discussion of the various suggestions, *seriatim*.

1. Every member of the profession knows what constitutes a "regular" or an "irregular" practitioner, but this should be clearly defined.

A physician in regular standing is one legally authorized to practise medicine, who assumes no sectarian designation, such as homeopathist, eclectic, etc., and who does not advertise or otherwise violate the rules of professional conduct embodied in the Code of Ethics.

An irregular practitioner is either one not legally qualified to practise medicine, or, if legally qualified, one who assumes to practise some special general system, or assumes some sectarian designation, as already indicated, or who advertises or violates, intentionally and habitually, the rules of professional conduct laid down in the Code of Ethics.

2. A physician should not meet in consultation with an irregular practitioner or be associated with such an one in the treatment of a patient; but he may properly examine a patient and give an opinion or advice to the patient or friends, or perform a surgical operation, in the case of a patient under the care of an irregular practitioner, without consultation or professional association with such practitioner.

3. A physician should obey, when practicable, all calls to cases of emergency, but should resign the case to the regular attendant as soon as possible. In case several physicians meet in cases of emergency, the patient or friends should be required to select which physician it is desired to retain.

4. A consulting physician should not displace the regular attendant during the progress of a case, unless with the attendant's full consent given in writing, and should avoid taking the place of the regular attendant as the family physician.

5. All consultations, when practicable, should be held in private.

6. The statement of the results of a consultation may be made to the patient or friends, either by the regular attendant or any participant in the consultation whom the regular attendant shall select.

7. Every consultant should be afforded the opportunity for a full examination of the case under consideration.

8. All discussions and opinions expressed in consultations should be kept confidential, if so desired

by the attending physician; and no private communications should be made by a consultant to the patient or friends.

9. Consultants should avoid trivial or unnecessary changes in treatment, and all changes in treatment should be made in the consultation.

10. In case of serious and irreconcilable differences of opinion in a consultation, the regular attendant should be allowed to retain the case, and the consultant or consultants who differ from him in opinion should withdraw, unless, at the request of the patient or friends, and with the consent of the attendant, the treatment be radically changed.

11. It is not decorous or professional for a physician to make friendly visits to a patient under treatment by another physician, except with the full knowledge and consent of the latter; and it is not professional for a physician to express any opinion in regard to the diagnosis or treatment of a case under the care of another physician, except in regular consultation.

12. It is unprofessional and unjust to other physicians to render gratuitous professional services to those able to pay suitable fees, except in cases in which personal relations or obligations render such a course practically unavoidable.

13. All differences between physicians, when they cannot be amicably adjusted by personal conference, should be referred, when practicable, to arbitration by physicians or medical societies, and recourse to courts of law should be avoided as far as possible.

14. A physician should never disclose any fact or circumstance ascertained by him, or communicated to him in his professional capacity, in regard to a patient, his family or friends, except with the full consent of the parties concerned.

15. The following acts on the part of a physician are unbecoming and unprofessional:

a. The granting of "interviews" on professional subjects to representatives of newspapers.

b. The sending of voluntary communications on professional subjects to newspapers.

c. The payment of commissions on fees for professional services.

d. The reception of commissions from pharmacists, surgical-instrument makers, opticians, or others on prescriptions or recommendations.

e. The taking out of a patent or the assumption of a trade-mark on any remedy, article of food or drink, hygienic preparation, surgical, obstetrical or scientific instrument or apparatus.

f. The giving of a certificate or recommendation for any remedy, article of food or drink, hygienic preparation, surgical, obstetrical or scientific instrument or apparatus, which can be used as an advertisement or part of an advertisement.

g. The use or recommendation of any medicinal preparation of which the exact composition or working formula is not published to the world.

h. "Resort to public advertisements or private cards inviting the attention of individuals affected with particular diseases; publicly offering advice and medicine to the poor gratis, or promising radical cures; or to publish cases and operations in the daily prints, or suffer such publications to be made; to invite laymen to be present at operations; to boast of cures and remedies; to adduce certificates of skill and success, or to perform any other similar acts."

16. Physicians holding public professional offices under a city, county, or State appointment or the General Government, may, in their official capacity, communicate, through the medium of newspapers, matters of interest to the public.

17. Physicians may issue for publication bulletins or certificates of disability, in cases of illness of public personages, with the consent of the parties concerned.

These rules of conduct are simple, distinct, and easily understood. If some such Code as suggested were adopted by the American Medical Association and recommended for adoption to the different State Societies, it is probable that it would meet the views even of the Medical Society of the State of New York. Should this happy result follow the labors of the Committee on Revision of the Code of Ethics, it would be difficult to find a logical basis for dissensions on questions of medical ethics.

MATTEISM EXPOSED.

MOST of our readers will remember that for several years a gigantic quackery-fraud has been carried on in England and on the Continent by the proprietors of the so-called cancer-cure of an Italian Count, MATTEI. We cannot understand why the enterprise was never transplanted to our hospitable shores. Our own smart folk have invaded England with less success than MATTEI & Co. would have found here.

For the great vogue of the MATTEI delusion in England, MR. STEAD, the famous London journalist, was largely responsible. There is no doubt as to the sincerity of the enthusiastic sponsor. Having been the means of robbing the people of millions of

dollars, temporarily discrediting medical science, and, after a false hope aroused, plunging thousands into despair, let us hope this "friend of the people" may have learned some little modesty.

MR. STEAD had never consulted any physician as to the pathology or therapeutics of carcinoma, had not an idea about the subject himself, and does not seem to have heard of the fact that no amount of ignorant human testimony as to the cure of disease has a particle of scientific value. He therefore (if the logic is clear) gave the "cure" the most extraordinary free advertisement, and the public rage and private profits both grew to great proportions. But the sincerity of MR. STEAD has proved the very means of exposing the humbug, and his shame must be as great as the disgust of the Matteists.

Chiefly through the editor's over-enthusiasm, a commission of eminent English physicians was appointed to supply and examine undoubted cases of carcinoma treated by the quacks. Great were the difficulties, and many the ludicrous obstacles interposed by the Matteists to seem willing to submit to the tests and yet to avoid the inevitable exposure that would follow genuine investigation. The story is told by DR. POTTER in the *British Medical Journal* of August 13th.

Five cases were finally accepted, and the treatment by the "electric potions" carried on for a year, the disease, of course, in each case growing steadily worse. A most laughable attempt was made to shirk the responsibility by the plea, often used in similar cases, that the members of the examining commission were "unbelievers," and with this specious nonsense even MR. STEAD's faith gave way, and for all sensible people the bubble was thoroughly pricked—but not, be it well noted, for the quack or his poorest dupes.

All that any sensible man can expect to do with quackery is to reduce it to its proper proportions, and allow it its proper *clientèle*. The electric fluid of the Matteists was analyzed and found to be simply, solely, nothing but pure water. The danger of this fraud was in its respectability and popularity. The apparently highest and most intellectual people, LADY PAGET, for example, were taking it up. Even members of the medical profession were, willy-nilly, becoming quiescent or acquiescent, some even using the "remedies." Now the danger is past, and the fraud will settle to its proper level, like astrology, and clairvoyance, and faith-healing, and all that.

We have lately been sagely lectured by an esteemed contemporary as to the unwisdom of ethical zeal against acknowledged popular and powerful medical humbuggery. The quacks, it is lamely said, will die a natural death, and opposition but stimulates them to further and renewed life. The example of the exposure of Matteism is most pat, and we leave our complacent critic with the lesson to ruminate upon. Progress and civilization, including the ease, knowledge, and usefulness of his own life, have been made possible only by "reformers" who saw the little truth, but who also saw the enormous untruth of his fallacious advice.

CHOLERA.

THUS far, cholera has been kept from our shores—unless the announcement be verified that five fatal cases have been detected in New York City. What the ultimate outcome of the present threatening will be is yet uncertain. The experiences of the present time ought prove extremely useful in anticipating a recurrence of the events of the past few weeks. The necessities of an adequate quarantine have already been pointed out—if, indeed, they needed pointing out. The extension of the powers of the President of the United States, defining his right to suspend immigration in times of threatened danger from infectious disease, without the necessity of at the same time placing an embargo on commerce, must also be a subject for early legislative enactment.

There are two other aspects of the present situation that demand special consideration. In the first place, it seems scarcely less than criminal that more than a thousand apparently healthy persons should have been kept on board pest-ships, together with those suffering from cholera, exposed to the risk of infection, under unfavorable hygienic conditions, with water of doubtful quality, without provision for change of linen, unable to sleep from fear or anxiety, and cut off from communication with their friends. Certainly these unfortunate tourists, particularly in the case of American citizens, were entitled to protection, as well as those threatened with danger on shore. Immediate provision should have been made for the landing of the apparently well that had been even remotely exposed to the danger of infection, and these could soon have been released if no symptoms of disease manifested themselves among them.

In the second place, the action of some of the steamship companies in accepting immigrant passengers from infected districts after the quarantine

of twenty days had been announced cannot be too severely condemned. As has been suggested by one of the newspapers, it would not under such circumstances be too severe a punishment to turn back to their sources of departure entire boatloads. It will thus be seen that it is absolutely necessary for the national authorities to dedicate a suitable and sufficient extent of ground for the purpose of isolating the sick from the well.

It is earnestly to be hoped that the lessons of the present situation will not pass unheeded by those to whom is confided the responsible duty of protecting the health and welfare of the people of the United States, of relieving them of unnecessary anxiety and of preventing loss of life and loss of trade.

CORRESPONDENCE.

THE REVISION OF THE CODE.

To the Editor of THE MEDICAL NEWS,

DEAR SIR: I do not desire to occupy your columns with a long discussion upon the value of our Code, but simply to emphasize both its necessity and importance. The Code was adopted by the American Medical Association in 1847, and for almost half a century has been the rule and guide of the regular profession in this country. The educated physicians of that day felt the necessity of a Code, to define distinctly our "duties to our patients," "to each other," and "to the public;" and for another reason, if not the most urgent—to defend them from the army of irregulars and quacks that were springing up all over the land, claiming equal rights, and seeking recognition from a generous public.

Nearly half a century has elapsed since the adoption of the Code, and the number of "pathies" and "isms" has increased *pari passu* with the regular profession and, I believe, because so large a part of our profession is either ignorant of the Code or does not carry out its provisions. Abandon it, and at once the greatest anarchy will prevail. There would be then no need for our colleges to raise the standard of medical education and to require a three or four years' course, instead of two, as formerly, for our country is already being overrun with medical colleges and schools of every grade and denomination. How much soever thoroughness and competency may be desired in the medical profession, they cannot be attained if we abandon our Code, for there will be admitted to our ranks both the uneducated and the unworthy. Rather abandon all scientific methods and medical schools than admit a Babel of therapeutics. We may as well admit the fact that we are yet young America, and the day has not yet arrived when we may lay aside this *lex supremis*. Admit, if you please, that among regularly educated physicians no code may be necessary, and that every individual who enters the profession does so from pure and generous motives, and will be actuated alone by a lofty spirit to do right and avoid doing wrong, and yet their remains a necessity for our Code, for our duties to each other and to the public are peculiar and intricate.

Laws are not made for those who would instinctively obey them, but for those who would disregard them but for the penalty attached. Our profession is largely made up of those who enter it from pecuniary motives, and your "Gideon's Band" must be small compared with this large class of workers.

Our Code is but the reflection of one of the greatest laws, human or Divine, "Do unto others as you would that they do unto you." Such a law needs no revision, and you may only mar by "adding to" or "taking from it." Examine, for a moment, the motives of those who would revise and really abandon our Code—for this is the question. Not long since the Medical Society of the great State of New York withdrew her allegiance to the American Medical Association, because of the article in our Code forbidding recognition and consultation with homeopathists. Will our Committee on Revision insert in our Code "*similia similibus curantur?*" or "that to be curative a drug must be capable of producing in the healthy system symptoms similar to those for which it is prescribed, and that it must be given in doses so small that the physiological effects cannot be perceived?" Or will they recommend that these aphorisms be added to our Pharmacopeia? Our dispensatories must then read that dynamization of medicines is proper, and that the millionth or decillionth part of a grain is more powerful than the whole! Shades of Wood and Bache, Chapman, Dunglison, and a host of fathers in medicine! Such are the teachings of the followers of Hahnemann, and constitutes one of the greatest fallacies of the nineteenth century. Whilst regular medicine is progressive and conservative, we dare not admit to its ranks the various "isms" that exist in our land and are anxiously seeking recognition. For almost a century homeopathy has striven for supremacy, and has attempted to build itself up upon the mistakes of the regular profession rather than upon scientific attainments. We are told, however, that Hahnemann's system has been greatly modified and improved by modern homeopathists, and that their practice is more rational. If so, why call it homeopathy?

Let them abandon their creed rather than that we should abandon our Code, and we can admit them to the regular profession only upon scientific attainments, and not *pro favori*. This branch of the profession has many attractions, and among its votaries are found the opulent and influential. It may well be understood how many of the regular profession are clamoring for consultation when large fees may be expected. Eclecticism, Keeleyism, and the "faith cure" may also be admitted, and then surely we will have no need of a code. Rather abandon the profession than our Code, which should be regarded as the Magna Charta of American physicians.

NEWS ITEMS.

Obituary.—DR. JOHN J. REESE, the eminent toxicologist, died September 4, 1892, at Atlantic City, seventy-four years old. He graduated from the art department of the University of Pennsylvania in 1836. Three years

later he graduated in medicine, at the same time receiving the Master's degree. In 1859 he was elected treasurer of the Philadelphia County Medical Society. He was president of the Medical Jurisprudence Society in the years 1886 and 1887. For a number of years Dr. Reese was visiting physician to St. Joseph's Hospital and Girard College. He was also medical supervisor of the Philadelphia Orphan Asylum from 1858 to the time of his death.

He was professor of Medical Chemistry in the old Pennsylvania College from 1854 to 1859. In 1865 he was elected professor of Toxicology and Medical Jurisprudence in the University of Pennsylvania. From 1861 to 1865 he was an Assistant Surgeon in the United States Army. Among the published works of Dr. Reese are "An Analysis of Physiology," "The American Medical Formulary," "A Manual of Toxicology," and "A Textbook of Medical Jurisprudence and Toxicology." He edited the seventh American edition of Taylor's "Medical Jurisprudence."

An Army Medical Board will be in session in New York City, N. Y., during October, 1892, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before October 1, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing C. Sutherland, Surgeon-General U. S. Army, Washington, D. C.

The Philadelphia Polyclinic will open its tenth Fall and Winter Term on Monday, September 26, 1892. Dr. John B. Roberts will deliver the Introductory Address, on "Injuries of the Hip-joint," at eight o'clock on the evening of the same day, in the hall of the college, 1818 Lombard Street, to which members of the profession are cordially invited.

Ontario Medical Journal is the name of a new candidate for professional favor, the first number of which bears the date of August. We fear that the *Journal* has started out wrong, not only in accepting questionable advertisements, but also in the publication of "reading notices."

Krafft-Ebing has been unanimously recommended to succeed Meynert, deceased, in the Chair of Psychiatry in the University of Vienna.

University of Berlin.—Virchow has been elected Rector of the University, and Jolly, Dean of the Medical Faculty.

BOOKS AND PAMPHLETS RECEIVED.

The Diseases of the Stomach. By Dr. C. A. Ewald, Extraordinary Professor of Medicine at the University of Berlin, Director of the Augusta Hospital, etc. Authorized Translation from the Second German Edition, with Special Additions by the Author, by Morris Manges, M.D. With 30 illustrations. New York: D. Appleton & Co., 1892.

Cardiac Outlines for Clinical Clerks and Practitioners, and First Principles in the Physical Examination of the Heart for the Beginner. By William Ewart, M.D. Cantab., F.R.C.P., Physician to St. George's Hospital, etc. Illustrated. New York: G. P. Putnam's Sons, 1892.

Two Cases of Extra-uterine Pregnancy. By J. A. Dickson, M.D. Reprint, 1892.

ORIGINAL ARTICLES.

CHLOROFORM INHALATION.[1]

BY H. A. McCALLUM, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE MEDICAL DEPARTMENT OF THE WESTERN UNIVERSITY, PATHOLOGIST TO THE GENERAL HOSPITAL, LONDON, ONT.

I DO not intend to go over the whole of the ground of so extensive a subject as the title of this paper indicates, but rather to present points for discussion, to describe what I have seen of the use of chloroform, and, so far as my observations bear me out, to criticise the report of the second Hyderabad Commission.

Here I would apologize in the words of Dr. Reeves, of Dayton, O., who in discussing the same report says: "In view of some of the names attached to these reports my efforts may be deemed presumptuous. I can only say that the day is past when a name caused acceptance of a doctrine which is not in accord with facts." In order to examine some of the deductions in this report it will be necessary to lay down what I consider the physiologic explanation of the terms "asphyxia," "blood-pressure," "cardiac failure," "syncope," and "shock," for it is to the varying interpretation of these that the differences in the findings of the several commissions on chloroform can be traced.

Asphyxia, when complete, is paralysis of the respiratory center. Its cause may be (*a*) the anesthetic alone, (*b*) the anesthetic plus venous blood, (*c*) venous blood alone. Now, it will be patent to anyone that respiration and circulation are so intimately associated that disturbed function of the one brings about changes in the other.

Is not respiratory embarrassment one of the most striking features of valvular disease? On the other hand, how soon must a muscle like the heart tire when it is supplied with venous blood? A poor circulation is a powerful factor in the production of asphyxia, and the rapidity with which this condition may be brought about, or the success of resuscitation, depends largely on the integrity of the circulatory apparatus.

Blood-pressure is regulated in one of the following ways: 1. By the heart directly, in the force and frequency of its beat. 2. By the heart indirectly, by sending impulses along the depressor nerve to the vaso-constrictor center, inhibiting its action. On this point Foster[1] says: "By means of this afferent nerve from the heart the peripheral resistance is, in the living body, lowered to suit the weakened powers of a laboring heart." 3. Emotions, shock, etc., may inhibit the vaso-constrictor center. 4. Chloroform during the first stage may so excite the nerve-centers that impulses from a heart receiving chloroform sent along the depressor nerve to them can set up changes in their unstable condition far beyond the range of the normal. In this way early syncope undoubtedly develops in some cases. 5. The vaso-dilator center may be stimulated, and the blood pressure lowered, but it is doubtful if this nerve-center ever plays any part in the production of syncope. I will attempt further on in this paper to explain the cause and method of the constant lowering of blood-pressure under chloroform.

Cardiac failure need not mean necessarily "primary cardiac arrest." Lowering of blood-pressure, dilatation of the heart-chambers and their incomplete mechanism as a force in the circulation, cessation of cardiac pulsations at or immediately following the cessation of respiration, all these indicate cardiac failure as a very important factor in the death of a patient. Cardiac failure, apart from that caused by anesthetics, as happens when a man makes a speech and falls back dead, or when another goes to bed apparently well and is found in *rigor mortis* in the morning, certainly points to the occasional occurrence of this form of death under anesthesia.

Syncope is sudden lowering of the blood-pressure sufficiently to induce stasis of the cerebral circulation and unconsciousness. Any one of the five causes given for decrease of blood-pressure may act strongly enough to produce syncope. The second is the most likely and frequent cause.

Shock, partial or complete, is inhibition of a number of nerve-centers. The vaso-constrictor center is always more or less involved. In this way syncope and engorgement of the abdominal vessels occur. Central shock may come from excessive doses of chloroform. Reflex surgical shock is a result of the reception of painful impressions in the central nervous system. If shock be reflex, it must have a functionally "beneficial intent" in it. I cannot conceive of any such intent, unless the impulse is one of pain. Here one can readily see such intent in producing anemia of the pain-centers, benumbing

[1] Read at the Ontario Medical Association, June, 1892.

[1] Text-book on Physiology, vol. i, page 325, fifth English edition.

them to impulses. It is a well-recognized fact in physiology that stimulation of an afferent nerve when the animal is under the influence of large doses of chloral brings about a fall of blood-pressure quite similar to that caused by stimulating the depressor nerve. If the animal is under the influence of urari, instead of chloral, a rise of blood-pressure follows such nerve-stimulation.

The condition of the central nervous system determines the rise or fall. If the action of chloral is like that of chloroform, then it is possible to have afferent-nerve stimulation (say of the sciatic)—a case of lowered blood-pressure that simulates shock. Syncope pure and simple is very difficult to separate at times from syncope due to shock. If the shock is to be attributed to some particular surgical manipulation, as evulsion of a toe-nail, an incision or crushing a pile, the syncope from such a shock must begin to manifest itself at once. The time taken in a reflex action is usually about one fifteenth of a second, and it would fall somewhere within this time. Two other points should enter into the decision, *i. e.*, the degree of anesthesia, and the intent or "organized tendency" of the reflex action. Shock will vary with the individual and the degree of anesthesia.

Having thus reviewed at some length the ground in dispute, I will refer to a few points in the report of the second Hyderabad Commission. The first that I am compelled to criticise is that involved in the statement that chloroform does not exercise a depressing effect on the heart in ordinary inhalation. As a result of its experience the commission freely admits that chloroform causes "a gradual fall of blood-pressure." This is the "constant effect," and this fall at times may even "become dangerous." Now a constant fall of blood-pressure must be due to the action of chloroform on the heart or on the nervous system. If, as the commission claims, the drug does not depress the heart, this fall of pressure must be due to its action on the vasomotor centers. Again, if the fall of pressure is due to the action of the drug on the heart, then chloroform must exercise a constant depressing effect on this organ, else why does the latter seek constantly to lighten its load unless to suit its depressed condition. The experiments of the commission were directed wholly to determine if there were a cessation or slowing of the beat of the heart to account for this fall. No effort was made to determine whether it were due to the drug acting on the medulla or not.

Dr. Lewis E. Shore,[1] together with Professor Gaskell, conducted some valuable experiments on dogs and rabbits that can leave no doubt about the cause of this fall of pressure. "In order to decide this question the following experiment was devised: Two animals were taken, and the arteries supplying the brain of one animal were gradually ligatured so that its brain was completely prevented from receiving blood from its own heart. The arteries, carotids or vertebrals, and in some cases both carotids and one vertebral, were then connected to the corresponding arteries of the other animal, and the brain thus supplied with blood, which returned by one pair of jugular veins cross-connected in a similar way. Care was taken that the brain was at no time without a supply of blood. Thus one animal, the *feeder*, was supplying its own brain by one carotid or one vertebral (and this always adequately sufficed), and also supplying the brain of the other animal, the *fed*. The blood-pressures of both animals were taken from the femoral arteries.

"When chloroform was given in the ordinary way, by inhalation, to the feeder, and the usual effect produced in that animal, namely, fall of blood-pressure and slowing of respiration, chloroform-carrying blood was also sent to the brain, and the brain only, of the fed animal, and there produced insensibility, a rise of blood-pressure, and slowing of respiration. When the fed animal, on the other hand, inhaled chloroform, a marked fall of blood-pressure was produced, and as the chloroform could not reach the brain, this could be due only to a direct action of the chloroform on the heart. If the brain of the fed animal, on the other hand, was richly supplied with chloroform by giving large doses to the feeder, the respiration could be brought into a very precarious condition without the slightest fall of blood-pressure, the chloroform depressing the respiratory center, but not the vasomotor."

Surely this throws a flood of light on this vexed question.

The inference is plainly this: That chloroform produces a constant lowering of blood-pressure because of its depressing action on the heart. As long as the result is the same, clinicians do not care whether this is effected by a primary arrest of the beat or by reason of the overtaxed organ calling on the vasomotor centers to let go their hold on the vessels. The heart controls blood-pressure directly or indirectly, and when the pressure is lowered it is because of a demand on the part of the heart itself. This fact having been established, "this depressing action on the heart is a source of danger always," and by a sudden increase of its effect (which might occur from some idiosyncrasy in the patient) primary cardiac arrest might occur. While it is not to be disputed that a lowered blood-pressure will occur in asphyxia, the greatest care should be exercised in accepting this as an explanation of some of the dangerous cases of lessened pressure seen by the

[1] British Medical Journal, November 21, 1891.

commission. It would seem as if the results were obtained too early to have been induced by asphyxia. It is possible that one might get such tracings from the drug and venous blood acting on the heart, when neither alone would yield any results. Careful examination of Professor H. C. Wood's tracings, showing "primary cardiac arrest," with the blood-pressure at zero, will convince any physiologist that Dr. Lauder Brunton is mistaken in his suggestion that these cases were obtained by reason of a clot forming in the manometer.

The next point in the report with which I strongly disagree is the one on "fatty hearts." The commission draw their conclusions entirely from "phosphorus hearts," a fatty degeneration that apparently does not correspond with the slow change resulting from multiple causes, as found in man. I think that I successfully proved last year that elasticity is a vital property of the ventricular wall, and that the endocardium contained as much elastic tissue as the aorta. Now, a few days of phosphorus will not in all likelihood alter the elastic tissue of the endocardium, leaving out of consideration the question whether it alters this tissue before the death of the animal. On the other hand, in many cases of fatty heart in human beings, the endocardium suffers alike with the myocardium, the result being often due to a process of malnutrition. Here, then, we have impaired elasticity coupled with impaired contractility, a predisposing cause to dilatation of all the chambers under the influence of the anesthetic. I deny that the commission had data on this subject from which they could formulate any conclusion. It is almost past belief that they could deliberately assent to the following statement: "Chloroform in no way endangers a fatty heart, although such patients die from very slight exertions or from fright."

Before closing the question of the influence that the heart exercises on the safety of chloroform administration, a few words concerning the cause of such safety to women in labor might be appropriate. To my mind, no small part of this safety is due to physiologic cardiac hypertrophy occurring in the last months of pregnancy. A second factor is no doubt intra-abdominal pressure on "the splanchnic area," preventing sudden syncope.

Leaving the commission and their findings, let me me say a few words about the dangers of chloroform, their causes, and how to treat them. Before doing so, for the sake of convenience in discussion, I will divide the subject into four stages: first, the stage of excitement; second, anesthesia; third, "profound narcosis," fourth, "recovery."

I will classify the dangers as those of asphyxia, syncope, shock, and "reflex cardiac inhibition" (this last may possibly be a variety of syncope, but I wish to speak of it separately).

In the first stage, asphyxia may arise from nasal or laryngeal obstruction. Spasm of the muscles of respiration, I can scarcely believe, ever led to a fatal result. If nasal obstruction is determined before giving the anesthetic, Dr. Butler, of London, Ont., uses cocaine to the parts. This will be more valuable in ether administration on account of the tendency of the latter to produce turgidity of this membrane. In laryngeal obstruction it is best to open the mouth and turn the patient on the side. With the patient in this position I am doubtful about the utility of pulling the tongue forward. The percentage of vapor in the inspired air is a matter of much importance in the eyes of some. I like a Junker apparatus, not because I think the percentage of vapor can exercise a very prominent part in the safety of the administration, but because of the convenience of this apparatus, and there being so little attention needed in the dosage, one is free to look after the patient. If, during vomiting, fear is entertained that some solid matters may enter the trachea, turn the patient on the side and open the mouth, but do not pull the tongue forward. There is a great deal to be said in behalf of the side as the proper position throughout the administration, the Hyderabad Commission to the contrary notwithstanding.

Syncope, as pointed out already in this paper, is common in the first stage, from the unstable condition of the nerve-centers, and it is most liable to happen if the head is elevated; from this come the dangers of operations under chloroform in the dentist's chair. I like to administer the drug without anything under the head; in fact it would be safer if the head were lower than any other part of the body. The treatment for this condition should be to lower the head, and keep it low, and to practise artificial respiration. Hypodermatic injections of digitalin form a valuable adjunct.

Reflex cardiac inhibition. It is a great blunder to think that inhibition will permanently arrest the heart. As Gaskell pointed out six years ago, inhibition means nutrition. The heart soon bounds on again with renewed energy. I have tried repeatedly in the presence of my class to produce death under chloroform by electric stimulation of the vagus, but have always failed. By opening the abdomen of the dog, and passing the hand up between the left lobe of the liver and the diaphragm, the heart could be felt plainly to be inhibited for only a few seconds at a time. I am, therefore, ready to agree with the commission when they say that "the theory that the danger of chloroform administration is slowing or stoppage of the heart by vagus inhibition is now shown to be absolutely incorrect."

The following facts, copied from notes from a typical case of inhibition occurring during teeth-extraction, may be interesting:

"A. B.: took some digitalis and strychnine the night before, and on the morning of the administration I gave chloroform with a Junker apparatus, but could not abolish the conjunctival reflex. I expected reflex inhibition, and asked one of the dentists to take the pulse. He replied, 'seventy, strong and full.' After six teeth were removed I gave him a few more drops to remove three additional ones. I held my finger on the radial artery throughout, and while pulling the last, a lower molar, the pulse suddenly disappeared, the face blanched, the ear applied to the chest of the patient detected no heart-sounds. This continued for about ten seconds, when I felt a return of the pulse, slow and wiry, at the rate of from twenty to thirty. The dentist took the pulse again at my request, and reported 'thirty, and fine as a needle.' The respirations were of a sighing nature throughout. Immediately the pulse ceased, I lowered the head of the patient and awaited events. He now passed into a distinct rigor; the pulse-rate was gradually coming up and he was becoming conscious. He asked for brandy, which was given him (the administration of any liquid is indicated because the act of swallowing abolishes the inhibitory action of the vagus on the heart). I then gave him a few drops of amyl nitrite, with the happy result of flushing the face and dilating the arteries."

It is in this apparently dangerous condition that the drug is useful, and nowhere else in chloroform inhalation.

Second Stage. The leading danger in this stage of anesthesia is the liability to run into the next stage, that of "profound narcosis." Dr. Balfour, of the General Hospital, London, Ont., speaking of this stage, said: "I have given chloroform to cases, one in particular, in which there appeared to be little or no second stage of comparative safety; no sooner would the reflex be abolished than alarming symptoms would show themselves." On the other hand, the majority of cases can stand considerable pushing of the drug after anesthesia, before profound narcosis is reached. In the vast majority of cases the road along which the patient is to be conducted in safety is wide. Rarely is it so narrow that the most skilful will fail to keep thereon. It is wise in some of these latter cases to complete the operation when the patient is in a condition as nearly as possible to incomplete anesthesia.

Third Stage. In profound narcosis, paralysis of the centers presiding over respiration and circulation is what will occur; the center the most frequent to give way is that of respiration. The second Hyderabad Commission apparently obtained nearly all of their fatal results in this stage—a fact that should greatly diminish the importance of their report. The best treatment here is that of hypodermatic injections of strychnine in full doses and artificial respiration.

Fourth Stage. Professor J. A. McWilliams,[1] as a result of some of the most carefully conducted experiments on chloroform, has demonstrated that the heart-chambers undergo dilatation with this drug, even when it is gently administered with plenty of air. He further points out that this may be greatly increased in a pathologic heart. I have myself seen these effects on the hearts of dogs. It appears to result from very incomplete emptying of the ventricles, and has no relation to vagus-inhibition.

Now, when returning consciousness establishes the line of communication between a dilated and laboring heart, on the one hand, and the medulla oblongata on the other, blood-pressure is sure to fall. Urgent messages from an overloaded and distended heart commanding relief often set up violent action in the nerve-centers. This is not to be wondered at when one remembers that these latter are intoxicated. The vaso-constrictor center, receiving cumulative stimuli from the depressor nerve from the heart, releases its hold on all the vascular areas. The patient is bled into his own vessels. The splanchnic flood-gates have opened wide, and the abdominal vessels become engorged. If the heart has been exhausted it will be an unwilling party to receive back the load it so freely threw off. Efforts at vomiting may express large quantities of blood into the right heart and re-distend it. Here syncope will be repeated, probably leading to a fatal result. The treatment is to lower the head, invert the patient, give hypodermatic injections of digitalin and strychnine in full doses, and to start artificial respiration, and keep it up for a long time. Other remedies are of questionable utility, and may contribute to the death of the patient.

There are reports of cases in which the patients died from the effects of chloroform many hours after the inhalation. In Kirk's cases,[2] seventeen hours had elapsed between the inhalation and death. Another is reported "who died some hours after the operation."[3]

At the end of this paper I present notes of the autopsy of one dying thirty-six hours after the administration of the anesthetic. I have clinical notes of one dying three days after. The operation was simple curetting of the uterus, and was done by a skilful specialist for hemorrhage due to a fibroid. It is a fair inference, that on account of the profound anemia that existed for months, there was fatty degeneration of the heart. The symptoms exhibited by the patient were those of "heart-failure."

Shock calls for morphine and heat. Brandy

[1] British Medical Journal, Oct. 11, 18, and 25, 1890.
[2] Ibid., July 11, 1891. [3] Ibid., July 4, 1890.

(after chloroform is very dangerous) can only be useful when given in narcotic doses. While on the subject of alcohol, I might mention that Professor Stephen Smith, of New York,[1] gets his patients thoroughly drunk with whiskey before giving the anesthetic, the patients "frequently jesting and singing on their way to the operation table." He claims that the patient gets quickly under the influence of the drug with a very small dose. He concludes by saying that "in the last ten years I have followed this method of preventing shock, and in no instance has that complication occurred. Alcohol is very much like chloroform in its physiological action, and, given before chloroform, will diminish the required dose of the latter." On the other hand, Professor H. C. Wood[2] has pointed out that in giving alcohol or ether during the stage of recovery, one runs a great risk of poisoning the patient. Alcohol before chloroform is probably beneficial, especially in habitual drunkards, in diminishing the dose of the latter, but given in the stage of recovery is wrong. Morphine and other narcotics, given before the anesthetic is administered, are said to lessen the dose of it.

Circulatory asphyxia. This mixed form of danger, in which asphyxia is brought about by inefficient circulation, is sometimes seen, and should be treated like syncope.

I would like to call attention to a few points among many directions in the giving of chloroform. Wood[3] called attention to the value of digitalis and strychnine in preventing the lowering of blood-pressure under chloroform. I have been using these two drugs before chloroform for the past year; sometimes I have given them for a few days before operation. If I could not administer these drugs six hours before the anesthetic by the mouth then they were given hypodermatically. They keep up a strong, full pulse, and diminish very greatly the "after-sickness" of chloroform.

In two cases recently, after having given strychnine hypodermatically when the patient was fully anesthetized, I discovered that it immediately antagonized the anesthetic effect of the chloroform. To such an extent was this the case that much larger doses of chloroform were required, and great difficulty was experienced in abolishing the conjunctival reflex. I consequently resolved thereafter to use digitalis alone before the administration of the anesthetic, and keep by me a solution of strychnine in a hypodermatic syringe, ready for an accident.

The second point is to watch well the respiratory movements and the face, as by this means one can see the first signs of cardiac failure in the gasping respiration and the pallid face.

The third point is that one ought not to be afraid to let the patient partly recover in intervals of the operation, if there are any such. Roughly speaking, this gives rest to a tired heart.

The fourth point is: Lower the head in all chloroform accidents. Cardiac failure may simulate asphyxia so closely that the haste and excitement will often leave the physicians (attending on the accident) in blind ignorance regarding the exact character of the danger they are treating. The only contra-indication to this inversion is an abdomen distended with ascites or a tumor which by pressure on the diaphragm may dangerously obstruct breathing.

There are cases that hold the elements of danger in themselves, and no care or skill can guard against a fatal result. The danger rests in the "receiver" not the "giver."

CASES OF DEATH.—Mrs. C., forty-eight years old; abdominal section for ovarian tumor and dermoid cyst, in the practice of Dr. Eccles, of London, Ont. She had no alarming symptoms until twelve hours after recovery from the anesthetic, when she appeared to sink from "heart failure," in spite of all medication, dying thirty-six hours after operation. I was asked to make the autopsy. I found the wound and the abdominal contents normal to the naked eye. The peritoneum was smooth and glistening. The right side of the heart held an antemortem clot of one ounce; fluid blood filled the right chambers, while the left side was empty; the valves were normal, and all the chambers dilated. The myocardium was pale, and tore easily. The coronary arteries presented well-marked nodular arteritis, and the left was almost obliterated one inch from its origin. On cutting a section of the ventricular wall and throwing it into a dish of water a coat of oil would immediately float on the surface. The microscope revealed well-marked fatty degeneration of the heart-muscle. There was evidence here and in other organs of general arteritis. Is this not a case of fatty heart receiving the fatal strain from taking chloroform?

MR. M., twenty-eight years old, in the practice of Dr. Fulton, of St. Thomas. A student assisted, but the greater part of the anesthetic was given by the doctor himself. It was a clamp and cautery operation for piles. The patient came out from under the drug some time between the removal of the second pile and its cauterization. The clamp remained on the pile for a few minutes, while the operator was in an adjoining room heating the iron. On his return some more chloroform was given to produce insensibility. It was then discontinued permanently. The second pile was now cauterized, the skin about the anus cleaned, and a dressing applied.

Dr. Fulton then examined the pulse, respiration, and face. On finding them normal, he gathered up his instruments, passing into the adjoining room

[1] THE MEDICAL NEWS, Oct. 11, 1890.

[2] Address on "Anesthesia," International Medical Congress, 1890.

[3] Ibid.

to wash them. The student in charge noticed the patient showing signs of recovery. Suddenly the pulse ceased and the face became deathly white. The doctor hastened to the side of his patient and found him trying to vomit. Natural respiration ceased shortly. The tongue was drawn forward and artificial respiration was practised for a few minutes. The head was lowered over the edge of the bed. Natural respiration returned for about one minute. Artificial respiration was resumed, and continued for about twenty-five minutes. Another medical man now arrived with a battery, which was employed with artificial respiration for some twenty minutes, but the patient was dead.

The Crown ordering an inquest, I attended the post-mortem examination at the request of Dr. Fulton. The following are the post-mortem conditions found:

Abdomen: Engorged abdominal vessels; some fluid blood in the cavity (due very possibly to the undertaker's needle wounding a vessel). Venous congestion of the liver (microscopic examination showed the central veins of the lobules and capillaries leading therefrom dilated, as in acute nutmeg liver; also malarial pigment plentifully).

Kidneys: Right, healthy; the left to naked eye showed changes from normal, viz., very imperfectly marked striæ. From one to four drams of milky fluid (which I think was pus) escaped on cutting into the kidney. Microscopic examination discovered round-celled infiltration that in some parts resembled the commencement of small abcesses.

Evidences of the removal of two piles; all the rest of the abdominal contents healthy to the naked eye.

Thorax: The pericardial cavity contained a dram of cherry-colored fluid. The right ventricle was engorged with fluid blood; the left held one ounce or more. The heart itself was "flabby," and all its chambers were dilated. The valves were apparently healthy (the hydrostatic test was not tried). Microscopic examination showed well-marked fatty degeneration of the muscle fiber.

The *lungs* were engorged (the apices were like the first stage of a pneumonia). On microscopic examination, sections taken from the apex showed the capillaries to be dilated and so injected that at many points rupture of their walls had taken place. By reason of this, many of the air-cells contained blood. The rupture of the capillaries might have been the mechanical effect of the artificial respiration or due to vasomotor influences. Examination of the trachea and larynx was negative.

Brain: The "vessels of the pia mater were injected in one part." The cord was not examined. (I was compelled to leave before the brain was examined by those attending to the autopsy.)

What was the cause of death? Before I answer that, I wish to state that the post-mortem examination alone should not be relied on exclusively. The clinical history of the case (the symptoms the man exhibited when he was dying) and the treatment must have no small part in determining the cause of death. The engorged right heart and lungs are neither constant nor pathognomonic post-mortem conditions of asphyxia.

Respiration is a pump to the right side of the heart, and exercises a powerful suction-force on the veins during respiration. Physiologists[1] are agreed that "were the heart perfectly motionless the working of this respiratory pump alone would tend to drive the blood from the venæ cavæ through the heart into the aorta." Thus, the pumping action of artificial respiration would engorge the right heart and lungs, so that this condition found post-mortem would represent a result of the artificial respiration, no matter what might be the cause of death. We are, therefore, compelled to rely to a great extent upon the clinical symptoms.

The sudden disappearance of the pulse, the blanching of the countenance, the failure to restore by artificial respiration (natural respiration returned for a minute, excluding paralysis of the respiratory center), leave no doubt of the occurrence of syncope in this case.

BARBER'S ITCH.

By WILLIAM S. GOTTHEIL, M.D.,
LECTURER ON DERMATOLOGY AT THE NEW YORK POLYCLINIC; ATTENDING SURGEON, DISEASES OF THE SKIN, NORTH-WESTERN DISPENSARY, NEW YORK.

THE term "barber's itch" is used by the laity to designate any disease affecting primarily the skin of the bearded portion of the face. The professor of the tonsorial art has been selected as the god-father of a number of distinct diseases whose sole bond of union is in location. This would be unfortunate for the professor, even if it were true that he was the real father and originator of the maladies in question. It is absolutely unjust if, as I think can be shown, the barber has nothing to do with them. He chances to shave a portion of the face prone to be attacked by certain affections, which also commonly occur elsewhere; and, since effect follows cause, and the shaving precedes the itch, therefore the barber causes the disease, and the term remains.

Now, the non-medical mind may be permitted to classify diseases according to their locality. It seems, of late, to have developed an intense hunger for fragments of medical knowledge; and the more indigestible the material with which this hunger is appeased the more likelihood is there of its being rejected or excreted unchanged. The anti-science nature of the ordinary primary and secondary education renders the appreciation of medical facts by the laity an impossibility. To really explain would mean to reëducate them. Since they must have medical knowledge, let them have it in suitable

[1] Foster, vol. i, fifth English edition, p. 219; Landois and Stirling, edition of 1884, vol i, p. 112.

form. Leave them their "barber's itch." But physicians should avoid the term; it is unscientific and meaningless.

It may be an imperfect observation, but my experience teaches me that a large proportion of medical practitioners are not more accurate than the laity in the diagnosis and designation of the diseases of the beard. Barber's itch is still an entity to them; the razor is still the medium of contagion; and arsenic internally is still the means of cure. This is sad, and, what is more important, it leads to non-success in treatment. Yet a little explanation will suffice to straighten out matters.

Three separate and distinct diseases are common upon the bearded face. There are others, but they are of rare occurrence; and others that occur primarily on hairless portions, and may extend to the beard; and still others to which the integument covering the jaws and neck shares a liability with the rest of the dermal covering. These we may leave unconsidered; their rarity and their other symptoms remove them from the category of barber's itch.

The three diseases commonly seen upon the bearded face are:

1. Eczema barbæ, or ordinary eczema.
2. Perifolliculitis barbæ, or sycosis non-parasitica.
3. Trichophytosis barbæ, or sycosis parasitica, or sycosis, or ringworm.

Let us briefly consider their distinguishing features.

1. *Eczema barbæ* does not differ essentially from eczema as it occurs upon other portions of the body. It is a superficial, catarrhal inflammation of the skin, slightly modified by location. It is not necessarily confined to the hairy parts, since the capillary structures are not primarily involved. Hence it may spread from behind the ears, or from the alæ nasi to the bearded face or lip; or, beginning on the hairy skin, it may involve the lips and nose and ears—favorite seats of the eczematous process. The integument affected is reddened and swollen, and secretes abundantly the peculiar gummy serum characteristic of dermal catarrh. The hairs are matted together, and, with the serum, form dry, brownish crusts. In every case, however, the skin itself is intact; a catarrhal inflammation never causes ulceration or destruction of tissue. Removal of the gummy crusts discloses a reddened, inflamed, weeping skin, but no cicatricial tissue or destruction of the hairs. The patient complains much of the itching, as well as of the disfigurement and discomfort caused by the scabs.

2. *Perifolliculitis barbæ* rejoices in as many names as does the heir to a European throne. One of the commonest is sycosis, either alone, or with the adjunct "non-parasitic." This name is to be rejected. It does not describe the disease, and it leads to endless confusion with parasitic sycosis. Both maladies, in fact, are called "sycosis," simply, by different authorities. Perifolliculitis, on the other hand, is descriptive and unmistakable, and it places the malady in its natural relationship with perifollicular inflammations of other portions of the skin.

Perifolliculitis of the beard consists of a pustular inflammation affecting the hair-follicles and the tissues in their immediate vicinity. It therefore commences in the beard, and is strictly limited to it. It begins with the appearance of a few red, conical papules, each of which has a hair implanted in its center. The skin between the papules is unaffected. The cell-exudation soon leads to pus-formation, and we have the characteristic lesion of the disease, an inflammatory pustule pierced by a hair. These hairs, though firmly implanted during the early papular stage, are, of course, loose during the later pustular period, extraction being then painless, the entire hair-sac lying loose in the minute abscess. Not every hair of the area affected is involved, so that there are always healthy tissue and normal hair between the diseased glands. But each hair-follicle affected is destroyed; a minute scar takes its place; other follicles in the neighborhood are subsequently affected; and so, finally, extensive areas may be denuded of hair, and the place of the skin be taken by a thin expanse of cicatricial tissue.

3. *Trichophytosis barbæ* is known as parasitic sycosis (a name to be rejected for reasons already given), and as tinea barbæ, and is simply a ringworm of the beard. It may or may not coexist with ringworm of neighboring or distant parts of the body. When fully developed, its appearance is quite characteristic. The hair of the beard being very deeply implanted, reaching far down into the subcutaneous connective tissue, the growth of the parasitic fungus is not interfered with by the connective tissue of the cutis; it develops freely, and soon leads to the formation of large, deep-seated nodules and tubercles. These masses are characteristic. The surface of the skin may be normal in some places, whilst in others it is fissured, inflamed, or desquamating. The hairs issuing from the nodular masses are broken off close to the skin, and are frayed at their ends, as in ringworm of the scalp. Suppuration around the follicles and permanent destruction of the capillary structures result.

These three maladies, then, constitute the unscientific entity known as barber's itch. The differences between them are usually so marked that the diagnosis is easy.

How are they to be avoided? If the hygiene of the barber-shop were all that is necessary, our task would be an easy one.

Eczema of the beard is in no sense a contagious

disease. It has never been caught by one patient from another suffering from it; it is not inoculable. Yet more than half of the cases of barber's itch are cases of simple eczema. Neither the barber nor any of his customers has anything to do with it.

Eczema of the beard, like eczema elsewhere, is due to certain external and internal conditions. External irritants, chemical or mechanical, will cause it; and an acrid nasal discharge is responsible for a considerable number of eczemas of the upper lip. The internal causes are not very definite; but it is agreed that dyspepsia and inefficient renal action predispose to dermal catarrhs.

The avoidance of this form of barber's itch is, therefore, dependent upon the avoidance of certain external irritants and the care of the general health. Improper—*i. e.*, too strongly alkaline—soaps are especially to be avoided, and the digestive and renal functions should be kept in order.

Nor is perifolliculitis of the beard a contagious disease, save in the limited sense that all pus may be contagious under certain conditions. Irritating powders and cosmetics, exposure to dust, or to intense heat, are the causes of the malady, which is especially likely to occur in those in whom the hair of the beard is stiff and wiry. A localized or mild eczematous condition often causes so much irritation that the finger-nails are freely used, and by these foci of purulent infection pus-organisms are implanted in the hair-follicle. Thus eczema and perifolliculitis frequently coexist, but the predominance of one or the other morbid process is generally marked.

The prophylaxis of perifolliculitis consists, of course, in the avoidance of the agencies that cause it. The face-powders used after shaving are undoubtedly responsible for some cases. Thus, again, in this second variety of barber's itch the barber is entirely innocent.

Ringworm of the beard, the third and last variety, is a frankly contagious disease. Whether or not there is more than one variety of the trichophyton parasite is a question still under discussion; but ringworm of the beard is always derived from another case of ringworm, and this malady is sometimes carried from one person to another by the barber. I say sometimes; I might say rarely, for the chances of contagion in this manner are small. The razor itself touches the skin only with its edge, which is frequently wiped and stropped; the fungus could hardly adhere to its blade. The lather-brush, the towels—but especially the barber's hands and finger-nails—are the mediate carriers of the contagion.

The prophylaxis is cleanliness; boiling of the towels; thorough cleansing of brushes, or, better still, individual brushes and cups; the use of the nail-brush on hands and finger-tips after each shave; with these ringworm of the beard may surely be avoided. There has been improvement in the hygiene of the barber-shop of late years, but enough cheap and careless ones remain to maintain in our dispensaries and clinics a steady, though small, stream of cases of trichophytosis barbæ.

And now as regards the cure of these diseases of the bearded face. They are frequently obstinate, prone to relapse, and annoying to the physician. An accurate diagnosis is necessary, for in certain essential particulars the treatment required differs in these three maladies.

Certain general rules may be laid down. The general health must be cared for; the gastro-intestinal and renal functions must be examined and regulated; sources of irritation—bad soaps, dusting-powders, exposure to dust and to the inclemencies of the weather—must, if possible, be eliminated. Nasal and aural discharges must be cured.

Treatment of Eczema of the Beard.

1. *Dietetic.* Put patients of full habit, hemorrhoidal tendencies, and prone to excesses at the table, upon a carefully regulated diet, mainly vegetable, with meat but once daily, and no alcoholics or coffee or tea. In obstinate cases a milk and farinaceous diet exclusively gives brilliant results. On the other hand, anemic patients should be put on a full, roborant diet.

2. *General.* Saline purgatives should be freely used in the plethoric cases, especially in the form of the natural waters. Anemic cases should have tonics, bitters, cinchona, iron, and strychnine. Alkaline diuretics are indicated in almost all cases, as:

℞.—Potassii citrat. . . . . gr. xx.
Infus. tritici repentis . . . ℥ss.
Infus. digitalis . . . ℥ss.—M.
S.—Twice daily.

Or,

℞.—Potassii acetat. . . . . gr. xx.
Spts. æther. nitrosi . . . ℥ss.
Syrup. aurantii . . . . ℥ss.—M.
S.—Twice daily.

Both are to be given in large quantities of water. Arsenic is useless, even in chronic cases.

3. *Local* treatment is most important. Remove all crusts by soaking with olive oil, and, if necessary, by means of soap and warm water; but thereafter, as much as possible, avoid the use of water, which is irritant. Cut off the hair of the affected part to facilitate treatment. Apply one of the following ointments:

℞.—Bismuthi oxidi . . . . ℥j.
Glycerini . . . . . ℥ss.
Ungt. aquæ rosæ . . . ℥j.—M.

Or,

℞.—Zinci oxidi . . . . ℥j.
Acid. oleici . . . . . ℥ss.
Petrolati . . . . . ℥ss.—M.

Zinc paint affords a thorough protection, and is very soothing:

℞.—Zinci oxidi . . . . ℥ij.
Mucil. gum. arabic. . . . ℥ss.
Glycerini . . . . ℥ss.—M.
S. Apply with a brush.

In the later, chronic stages, use the diachylon ointment; if the scaling still persists, tar or resorcin must be employed, as:

℞.—Ol. cadini . . . . ℥ss.
Pulv. zinci oxidi . . . ℥ij.
Amyli . . . . . ℥ij.
Adipis . . . . ad ℥j.—M.
Or,
℞.—Resorcini . . . . gr. xv.
Lanolini . . . . ℥j.—M.

Treatment of Perifolliculitis Barbæ.

In a purely local disease, dietetic or general treatment is not necessary, save in so far as applies to the removal of any irritant—cosmetics, snuffs—that may seem to have some etiologic relationship to the malady. Cod-liver oil given internally seems, as in so many other affections, to control the tendency to pus-formation; it should be given freely in obstinate or extensive cases. Calcium sulphide is absolutely useless.

Local treatment. The beard or mustache must be removed from the area affected, as it interferes with treatment. Shaving is liable to further irritate the skin and to cut off the hair so short that it buries itself in the inflammatory papule and cannot be extracted. Have the hair simply cut close. Now epilate every affected hair in the area. If there are too many for one sitting, take them in sections. Hair-bulbs surrounded by pus are loose, and can be removed without causing pain; the proceeding is as rational as to open a furuncle and to remove the splinter of wood that causes it. Even before suppuration has set in, every hair that is evidently the center of inflammatory action should be pulled out. By this means a chief source of irritation is removed and free exit is afforded the sero-pus. In this way, destruction of the hair-follicles and their surroundings, as well as baldness and scarring, are best avoided.

For this purpose a forceps with flat, unserrated blades is more convenient than the ordinary kind Each hair must be extracted singly, traction being made in its axis. The operation is painful, but necessary; it should be repeated at intervals by the physician, since neither the patient nor his friends will have sufficient skill and fortitude to do it themselves.

The way being thus prepared, soothing ointments are to be used. A favorite of mine is the following, which is sedative and very bland:

℞.—Tinct. opii . . . . ℥ss–℥j.
Acid. carbol. . . . . gr. x.
Ungt. aquæ rosæ . . . . ℥j.—M.
S.—Apply twice daily; keep on constantly.

A little later, when the first acute stage has passed, astringent applications are in order. Thus:

℞.—Ungt. diachyli . . . . ℥ss.
Ungt. zinci oxidi . . . ℥ss —M.
Or,
℞.—Hydrarg. chlor. mit. . . . ℥ss.
Petrolati . . . . . ℥j.—M.

Finally, the following may be employed:

℞.—Ichthyol. . . . . ℥ss.
Lanolini . . . . . ℥j.—M.

It is well not to forget, and not to let your patient forget, that perifolliculitis of the beard is frequently a very obstinate disease.

Treatment of Trichophytosis Barbæ.

Here, again, general measures are useless.

Local treatment. Remove the crusts with olive oil, warm water, and soap; then get rid of the excess of hair by cutting—not by shaving—for the reasons already given.

If epilation of the *affected* hairs is required in perifolliculitis, *all* of the hairs must be removed in ringworm. It is impossible to tell with certainty which hairs are healthy and which are diseased. Hence every hair of the affected area and for some distance around it must be pulled out. The process is painful, for the hairs are often firmly implanted; nor does cocaine, either applied externally or injected, help matters much. The pain must be borne, for without removing the hair and opening up a route for our remedies no parasiticide can penetrate to the depths of the follicle in which the mass of the fungus is growing.

Even after epilation it is sometimes difficult to find an agent strong enough. Go at once to:

℞.—Hydrarg. chlorid. corrosiv. . gr. ij–iv.
Glycerini . . . . . ℥j.
Aq. cologniensis . . . ℥j.—M.
S.—Apply twice daily.

Start with the weakest solution, and rapidly increase its strength. For small diseased areas emplastrum hydrargyri or unguentum hydrargyri does fairly well. A solution of the oleate of mercury—from 5 per cent. to 10 per cent.—in oleic acid is of use, and should be painted on twice daily. But in almost all cases we are finally compelled to have

recourse to mercuric chloride, and we might as well start with it. A twelve-grain-to-the-ounce solution has proved necessary in some few cases; of course, such strong solutions must be applied by the physician himself; they cannot be entrusted to the patient.

25 WEST FIFTY-THIRD STREET.

THE PRODUCTION OF IMMUNITY IN GUINEA-PIGS FROM HOG-CHOLERA BY THE USE OF BLOOD-SERUM FROM IMMUNIFIED ANIMALS.[1]

BY E. A. DE SCHWEINITZ, PH.D.,
BIOCHEMIC LABORATORY, BUREAU OF ANIMAL INDUSTRY, DEPARTMENT OF AGRICULTURE, WASHINGTON, D. C.

THE important results obtained by Behring and Kitasato, Tizzoni and Cattani, Klemperer and Klemperer, and others, with diphtheria, tetanus, pneumonia, etc., led me to undertake a series of experiments upon guinea-pigs for the purpose of studying the effect of the blood-serum from animals immune to hog-cholera. As a source for the blood-serum, I used guinea-pigs that had been immunified by means of the albumose extracted from artificial hog-cholera cultures, and then exposed to the disease by inoculation with the virulent germ.[2] From this latter inoculation the animals had not suffered, and at the time of use had been well for several months. The blood was drawn from the carotid artery into a sterile test-tube, and defibrinated by means of a sterilized glass rod, the overlying serum then being used for injection. Precautions were taken that the blood did not become contaminated while being drawn, and the absence of germs from the serum was carefully tested.

The experiments were as follows:

Exp. 1. Two guinea-pigs, weighing each about one pound, received three c.c. of this blood-serum by a single injection on the inner side of the thigh. This injection was followed by a slight rise in temperature, but no local lesion at the point of injection, though there was a slight inflammation of the skin for four or five days. After ten days these pigs, together with two checks, were inoculated in the thigh with $\frac{1}{10}$ c. c. of peptonized beef-broth hog-cholera culture, one day old. The checks died in seven days. The autopsy showed characteristic hog-cholera lesions; the hog-cholera bacteria in the spleen were abundant. Both treated animals apparently recovered from the inoculation. Four weeks after the inoculation one of the pigs became paralyzed in the hind legs, and finally died five weeks after the inoculation. The autopsy showed the organs to be apparently normal, except for a few small dots on the surface of the liver. Culture showed an absence of hog-cholera germs.

The second treated pig was found dead three months after the inoculation. The autopsy again showed the organs apparently normal, except for a slight injection of the intestines.

There had in these two cases been then a considerable resistance to the disease from a single injection of the blood-serum. As the germ could not be detected by cultures, and the organs, further, were apparently normal, it is probable that some other cause than hog-cholera caused the death of the animals.

Exp. 2. The experiment was repeated upon exactly the same number of animals, and in the same way, with the result that the pigs treated with the blood-serum recovered entirely, while the checks died. The autopsies of the checks showed characteristic hog-cholera lesions and the germs were abundant in spleen and liver. The experiment repeated again gave the same results—a recovery of the treated animals and the death of the checks.

This work, taken in connection with my earlier results in immunifying guinea-pigs,[1] made it apparent that the blood-serum was a potent factor in the production of immunity.

While in the case of the use of the albumose extracted from the artificial sterilized cultures, or in the use of the simply sterilized cultures, from ten to fifteen c.c., or the equivalent, were required for immunization, here only three c.c. of the serum were necessary.

Treatment of Guinea-pigs Inoculated with Hog-cholera with the Serum from Immunified Animals.—I next tried to cure guinea-pigs with the blood-serum:

Several pigs were taken, and all inoculated with $\frac{1}{10}$ c. c. hog-cholera culture, one day old. Two days afterward two of these animals received an injection of 1.5 c.c. of the blood-serum from an immunified animal. The other animals were reserved as checks. The injections with the same quantity of serum were repeated after two days. The result of the experiment was that while the checks died within ten days, the treated animals resisted for from a week to ten days longer, finally, however, succumbing to hog-cholera, as proved by the autopsies.

The experiment was repeated with the same quantity of material, and in the same way, and I succeeded in saving one of the animals, the recovery being entirely satisfactory. All of the checks died. This cure may have been accidental.

At present I am making a more extended series of experiments in this line, beginning the injections with the blood-serum within twelve hours after the infection, and repeating them more frequently. In

[1] THE MEDICAL NEWS, October 4, 1890.

this way it may be possible to effect a cure in every instance.

Just at this point in my experiments the copy of Pasteur's journal (*Annales de l'Institut Pasteur*, May 25, 1892,) reached my hands, in which a series of experiments upon rabbits is described by Metschnikoff, with the germ which he considers to be identical with that of our hog-cholera. His results were the same as those I had obtained, an easy immunization by means of the blood-serum. Metschnikoff's injections of the blood-serum were all intra-venous and repeated several times. My injections were subcutaneous. The practical results, however, in both cases were the same.

A few tests were made in order to see if the action of the blood-serum was due to its germicidal properties. These experiments showed that the serum *outside of the body* did not exert a germicidal action on the hog-cholera bacillus, and on this point they also agree with Metschnikoff's work.

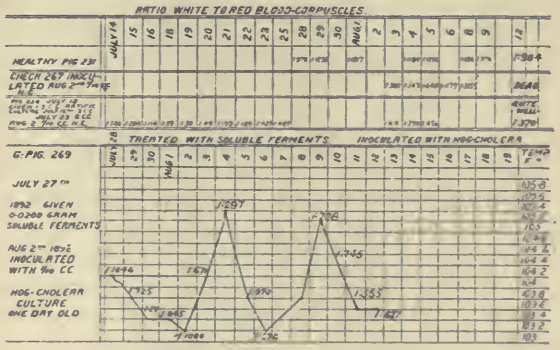
At the same time that the blood-serum experiments were being carried on I had a number of guinea-pigs that were being immunified with the albumose extracted from milk-cultures, the products from purely artificial mineral salt and glycerin-cultures, and with the soluble ferments that I have recently obtained from the hog-cholera cultures.

In view of the observations of Roemer[1], Neisser[2], Canon,[3] Botkin,[4] and Tschistowitsch,[5] I thought it would be of interest to learn if there was a noticeable increase in the number of white corpuscles in the blood of guinea-pigs inoculated with the germ alone, and in the animals while being treated and after treatment, when inoculated.

The blood was taken daily from the ear of the animal, and the hemocytometer of Thoma-Zeiss employed for estimating the number of corpuscles. Toison's solution served for the staining fluid. Beginning twenty-four hours after each injection or inoculation, the counts were conducted till the animals either died or recovered from the disease. To serve as a check upon the number of white blood-corpuscles, a healthy animal was also used. Comparing the figures thus obtained, allowing for natural daily variation and individual error in counting, we find an increase in the number of white blood-corpuscles, both in the checks and in the treated animals. After the first injection for immunifying the animal, the white blood-corpuscles apparently increased, and then returned to the normal as the animal became well. When these same animals were inoculated, the increase of the white corpuscles and return to the normal were equally marked. In the checks, those inoculated with the germs showed a decided increase, and then decrease in the number of white blood-corpuscles, till the animal died. These results, though but preliminary as regards the disease of hog-cholera, may be considered as throwing some light on Metschnikoff's theory of phagocytosis.

While writing this article, Kanthack's[1] paper reached my hands. He reports observations upon the leukocytosis produced by the pyocyaneus-cultures, and sterilized cultures of the vibrio Metschnikovi. As his injections were made intra-venously and with fairly large amounts of the material, the increase in the number of leukocytes was more rapid. He observed, upon repeated hourly examination, first a decrease and then an enormous increase in the number of white blood-corpuscles. In my experiments this increase was not quite so marked, nor was the decrease at first noticed, but as the counting of the corpuscles was not begun till twenty-four hours after the injections, it would not have been observed.

In the appended chart is represented the relative number of white and red corpuscles, as found in a healthy guinea-pig, No. 231, in a check, No. 267, and in two treated and then inoculated pigs, Nos. 224 and 269. In the case of No. 269 the corresponding temperatures are also noted. I may take occasion here to acknowledge the help of my assistant, Mr. Emery, in the estimation of the leukocytes.



RATIO WHITE TO RED BLOOD-CORPUSCLES.
HEALTHY PIG 231
CHECK 267 INOCULATED AUG 2ND 1892
TREATED WITH SOLUBLE FERMENTS
INOCULATED WITH HOG-CHOLERA
G. PIG 269
JULY 27TH
1892 GIVEN 0·0208 GRAM SOLUBLE FERMENTS
AUG 2ND 1892 INOCULATED WITH 1/100 CC
HOG-CHOLERA CULTURE ONE DAY OLD

The results of my work show that there is an easy immunization of guinea-pigs from hog-cholera by means of the blood-serum of immunified animals, and that there is a possible cure of infected animals by a similar treatment. Further, they point to an apparent education of the white blood-corpuscles in the blood of guinea-pigs by means of the bacterial products.

The work agrees practically with that of Metschnikoff upon rabbits.

CAN CROUPOUS PNEUMONIA BE ABORTED?

BY THOMAS J. MAYS, M.D.,
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND VISITING PHYSICIAN TO THE RUSH HOSPITAL FOR CONSUMPTION.

IF one fact is more patent than another, it is that when the medical profession comes to deal with the treatment of croupous pneumonia it is like a rudderless ship in a storm at sea. Why this should be so is not easy of explanation. Here is a disease, constant in its pathology and morbid anatomy, and the physical signs and nature of which are well recognized, and yet the most opposite and varied forms of treatment are and have been advocated, and it is even taught by some of our latest text-books on practical medicine that the expectant or "let alone" treatment is productive of the best practical results.

This seems to be a startling state of affairs, although I must confess that until recently I had no special reason to believe that my work in this direction was followed by any better results than were to be expected by natural recovery from the disease. From later experience, however, which, I trust, will not prove altogether anomalous, I feel convinced that the skepticism that has invaded the profession concerning the utility of therapeutic art in pneumonia is not justified by what may be accomplished. The ground for this faith rests principally on the following detailed results that have been obtained in the treatment of two cases of acute pneumonia under my care in the Polyclinic Hospital. The principal treatment in these cases—which was, I believe, first suggested by Niemeyer—consisted in enveloping the affected chest-area in ice, and, although the cases are too few to warrant any extensive deductions, I think they clearly demonstrate that the local influence of a very low temperature is directly antagonistic to the pneumonic condition. I had long been accustomed to apply ice to the chest in pulmonary phthisis, for the purpose of controlling the acute exacerbations, and with exceptionally good results; hence I did not share in the widely prevalent fear that the application of ice in inflammatory diseases of the lungs is fraught with danger to the patient.

CASE I.—P., a colored female, twenty-five years old, came under my care November 24, 1891, with the following history: Four days previously, when her temperature, pulse, and respiration were normal, Dr. Baer removed her left ovary, which contained a large hematoma. On the morning of my first visit she had a temperature of 103.4°, and a physical examination showed that the lower parts of both lungs were in a state of consolidation, extending the higher upon the right. There was also evidence of pleurisy on this side. The temperature had risen rather suddenly, for on the morning of the 22d it was 99°, while on the evening of the 23d it reached the height of 103.4°, as already stated. On the morning of the 24th ice-bags were applied to the front of the chest upon the right, and to the lateral aspect of both sides of the chest, and, with few intermissions, were kept almost constantly applied for about two weeks. The temperature began to decline immediately after the ice was applied, and, excepting a slight rise on December 3d, sank to nearly a normal level on the eleventh day, as is shown by the following temperature table:

	Morning.	Evening
November 24th	103.4°	102.4°
" 25th	101.4	100.6
" 26th	100.0	99.8
" 27th	101.0	100.0
" 28th	100 8	100.8
" 29th	99.0	101.0
" 30th	101.0	99.8
December 1st	99.2	99.8
" 2d	99.6	99.8
" 3d	98.8	101.4
" 4th	98.5	99 8
" 5th	99.2	99 8
" 6th	98.6	99.8

Subsequently, the temperature remained practically normal.

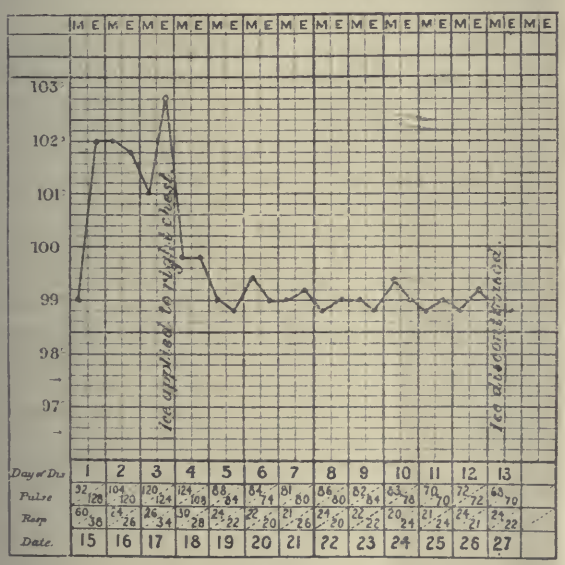
Simultaneously with the fall of the temperature there was a corresponding improvement in the physical signs and symptoms. The depressing effect of the ice on the temperature-curve was immediately shown after its application. When the ice was removed, as it was several times during the course of the disease, the temperature almost invariably rose. This partly accounts for the unsteady temperature-line between morning and evening, which is not shown fully in the foregoing figures—although, on the whole, the woman was of a nervous temperament, and this unquestionably influenced her temperature-curve in a measure. Her nervousness is indicated by the frequency of her respirations: these were 48 per minute at one time, and in four hours they fell to 24, and without any apparent cause.

In addition to the ice she received two ounces of freshly-expressed beef-juice alternately with half an ounce of beef-meal in coffee or chocolate, every two hours, and half an ounce of whiskey in a glassful of milk, every three hours. As far as drugs were concerned she received quinine and phenacetin internally in small doses, and an occasional hypodermatic injection of morphine to produce sleep and to alleviate pain.

In some respects this case was peculiar. There was no cough or expectoration, except on the seventh day, when several mouthfuls of blood were spat up. The woman suffered greatly from dyspnea, although the pulse never exceeded 120 in frequency, and usually oscillated between 90 and 106. It may be said that the defervescence was slow, but when it is remembered how prone any inflammatory

disease of the lung in the negro race is to run into catarrhal disease and become chronic, I think the result on the whole is rather gratifying.

CASE II.—F., a girl, eighteen years old, was first seen on June 17, 1892, when she presented the following physical signs: The pulmonary percussion-resonance was impaired over the whole anterior surface of the right lung, with dulness, approaching to flatness, over the whole posterior and lateral surfaces of the lung. Expiration was decidedly prolonged over the anterior surface from apex to base, and crepitant, subcrepitant, and some sibilant râles were heard over the posterior and lateral portions of the lung. The conditions manifested on the part of the left lung were normal, except that the breathing was puerile. There were abdominal pain, cough, mucous expectoration, and a temperature of 102.8°; the respirations were 34, and the pulse 124. On the afternoon of this day the right chest was well enveloped in ice-bags—a large one in front, and two at the side and posteriorly as much as possible. Another ice-bag had been applied to the head in the morning. Internally the girl received $\frac{1}{25}$ of a grain of strychnine and five grains of quinine every three hours. She was also given an ounce of fresh beef-juice every two hours, and milk and whiskey. On the morning and evening of the following day (18th) the temperature had fallen to 99.8°, and the physical signs were unchanged, except that the prolonged expiration had disappeared anteriorly and was replaced by crepitation. On the 19th the sputum was rusty-colored, and in the evening the temperature



was 98.8°. On the 21st there was a perceptible improvement in the pulmonary percussion-resonance of the whole lung. Very few râles were heard, except at the extreme lower part of the lung. The expectoration had become muco-purulent and rusty. On the 24th no râles could be heard at any part of the chest. The percussion-resonance was vesicular anteriorly and laterally, and but slightly impaired posteriorly. Expectoration had ceased. Strychnine was discontinued on account of a manifestation of its physiologic effects. On the 26th the percussion-resonance continued to be slightly impaired in the right interscapular region. No râles were heard. The respiratory murmur was normal over the whole lung, excepting for slight impairment in the interscapular region.

On the 27th the ice was discontinued, and on the 6th of July, after progressive convalescence, the girl was discharged. The chart illustrates the temperature, pulse, and respiration of this case.

In conclusion, I do not desire to be understood as believing that ice will be found a panacea in pneumonia, but I think the histories of the two cases here related show that cold applications to the chest have a direct, beneficial action on the pneumonic process, not only in the sense of limiting its extension, but in dissipating it. This was especially well demonstrated in the second case, in which the local condition, as indicated by the physical signs, improved immediately after the ice had been employed.

One other feature may be referred to in this connection. In neither of these cases was there anything like a critical period, but merely a more or less rapid subsidence of the local and general disturbance—giving one the impression that, if the disease was not aborted, it received a decided check, and was certainly not allowed to pursue an even and uninterrupted course.

Probably not the least important lesson that may be learned from these cases is that the fear that cold or ice applications in pneumonia are detrimental to the patient is entirely unfounded, and, if this demonstration will serve to allay this apprehension, I feel that these cases have not been reported in vain.

CLINICAL MEMORANDA.

A CASE OF ABDOMINAL NEPHRECTOMY:

With Practical Lessons Thereon.[1]

BY SCHUYLER C. GRAVES, M.D.,
VISITING SURGEON TO ST. MARK'S AND THE U. B. A. HOSPITALS, GRAND RAPIDS, MICHIGAN.

IT is not my purpose to present an exhaustive paper on the subject of nephrectomy. I desire, on the contrary, to report, simply and briefly, the history of a successful case that has occurred in my practice.

Let the fact, then, that the operation is one of considerable interest to surgeons, on account of its comparative rarity and the high mortality-rate with which it is associated, be my excuse for making this report.

The case presents several features of peculiar interest in pointing a moral that, I trust, may spare others many moments of anxiety, which it has been my unfortunate lot to experience.

[1] Read before the Surgical Section of the Michigan State Medical Society, at Flint, Michigan, May 5, 1892.

Mrs. C. S., twenty-nine years old, eight weeks after the birth of her only child, a boy of about seven, noticed a lump in the left side, as large as the palm, and not painful except upon pressure.

Dr. Martin, the first physician consulted, saw the case one and one-half years after the tumor had been discovered. He came to the conclusion that the tumor was splenic, and prescribed tonics and applied the galvanic current.

The patient states that the tumor seemed to grow smaller during the year of current treatment, but increased in size as soon as the treatment was withdrawn.

The patient then had no particular treatment for about two years, at the expiration of which time she consulted Prof. McGraw, at Detroit. Dr. McGraw made a diagnosis of enlarged and dislocated spleen, and recommended non-interference. He declined operating and advised the patient to return home, giving her, at the same time, some medicine which he said he hoped would check the growth of the tumor. He did a perineorrhaphy upon the patient, however, before she left the Detroit hospital, in the hope of building up a somewhat shattered constitution. This was about two years ago.

Time went on, and no particular change was noticeable in the tumor or in the general health.

In January of the present year the patient fell into the hands of Dr. B. J. Zudzense, of Sparta, Kent Co., Mich., who kindly referred the case to me.

During all of these years the health of Mrs. S. had been feeble; constipation had been the rule; the appetite was at times poor and then abnormally great; she slept badly for weeks at a time; the menstrual functions were normal.
